Text S1. Brief analysis of the climate change applied for PGW simulations

The changes applied, under the RCP 8.5 scenario, represent a major warming of the region. At the ground level a larger temperature increase is seen over land than over the sea with local maxima over the Arabian Peninsula and north-western Asia (Fig. S1a). The warming peaks at the upper troposphere (~300 hPa), where maximum values are near the equator, and is stronger in fall compared to spring (Fig. S1b-c). It is interesting to note that the warming in the upper troposphere is enhanced during fall, which may increase the static stability compared to winter and spring. The pattern of sea level pressure resembles the surface temperature change (with an opposite sign) and exhibits a maximum over the central Mediterranean, and a minimum at the Arabian Peninsula and north-western Asia, implying a decreased frequency of MCs, or a general decrease in sea-land pressure gradient. These changes are in concert with previous studies (e.g., Giorgi and Lionello, 2008; Seager et al., 2019; Tuel et al., 2021; Tuel and Eltahir, 2020). The moisture field is only slightly increased over the Mediterranean region, with larger increases in fall than in spring, and farther to the south in equatorial Africa (Fig. S1b,d). Combined with decreased zonal wind at both the lower and the upper tropopause, this suggests a decrease in moisture flux into the eastern Mediterranean.

Table S1: Heavy precipitation events (HPEs) analysed in this study. Further details on the identification of events are described in Armon et al. (2020). Durations for which each of the HPEs were identified are marked with and X.

HPE #	Start time*	End time*	Synoptic classification[#]	HPE duration [h]						
				1	3	6	12	24	48	72
1	2-11-1991 9:00	5-11-1991 9:00	MC	X	X	X	X	X	X	X

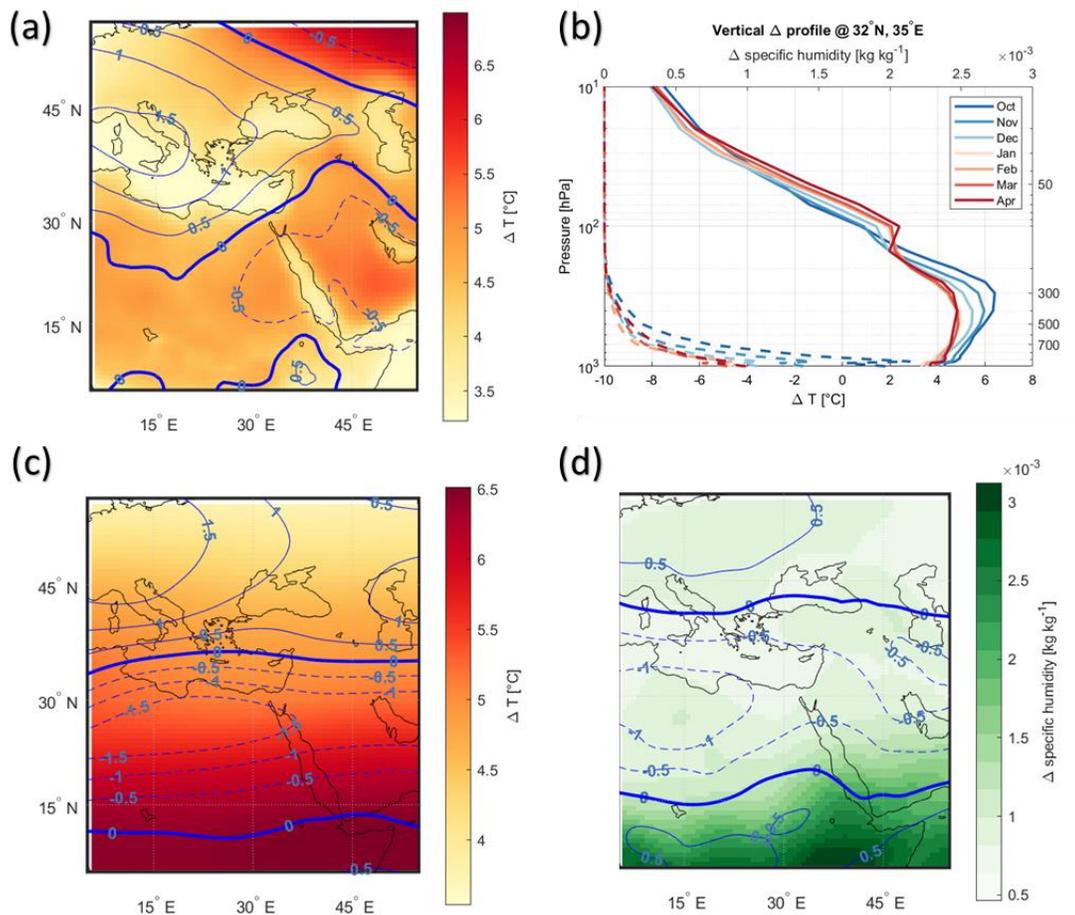

Figure S1. Examples of changes applied in "Future" (PGW) simulations based on ensemble mean of 29 CMIP5 models (Table S3). (a) Average change during the months with HPEs analyzed in this study (Oct through Apr; Table S1) in surface temperature (colors) and in sea-level pressure (contours). Dashed contours in panels a, c and d are negative signals. (b) Monthly vertical profiles of the change in temperature (solid lines, bottom horizontal axis) and in specific humidity (dashed lines, top horizontal axis) at the center of the study region (32°N, 35°E). Vertical changes were applied in each of the pixels along the study domain. (c) Average change (Oct through Apr) in upper-troposphere temperature (300 hPa; colors) and in the zonal (west-east) wind (contours). (d) Average change (Oct through Apr) in lower-troposphere specific humidity (850 hPa; colors) and in the zonal (west-east) wind (contours).
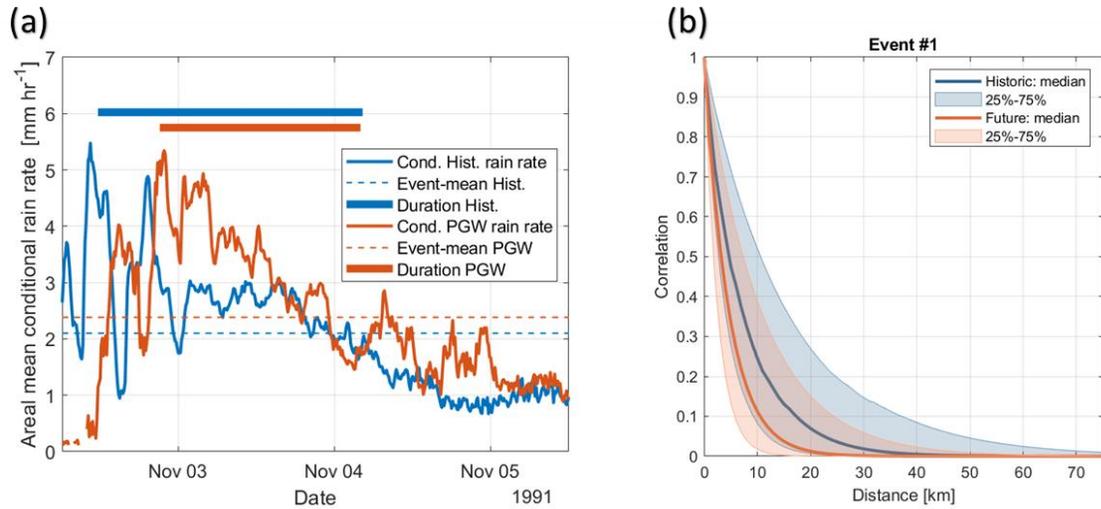

Figure S2. Additional rain properties of HPE #1. (a) Areal mean of 10-min conditional rain rates throughout the event. Dashed lines are the event-average values, and the bold, thick lines represent the duration of the event (the interval in which the central 90% of rainfall precipitated). (b) Autocorrelation structure of the 10-min convective rain fields for the first heavy precipitation event (HPE) in our collection, 2-5 Nov 1991. Curves are median values across 429 convective rain fields in the historic simulation (blue) and 407 in future simulation. Shaded areas represents the 25%-75% quantiles from each simulation.
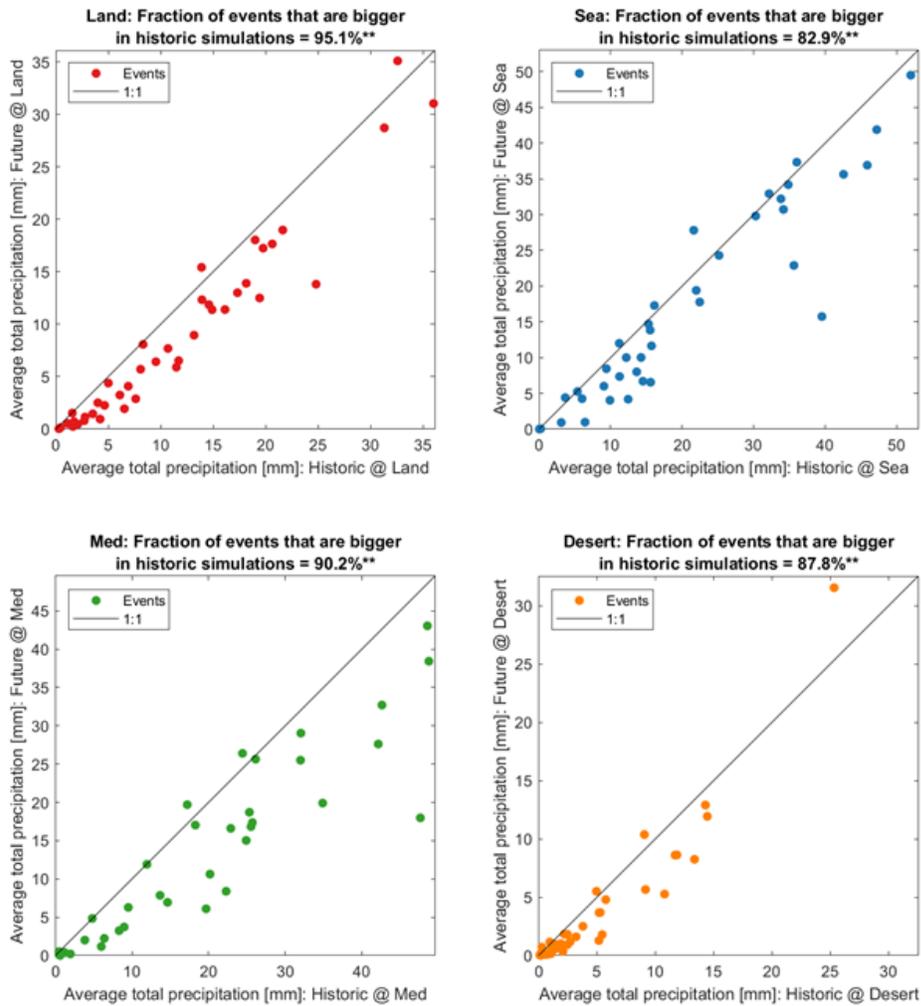

Figure S3. Comparison of future and historic rainfall accumulation of each of the 41 HPEs analyzed (as in Fig. 4a), computed separately for each of the sub-regions (Fig. 1b). Statistical significance, marked with ** in the panel titles, is based on paired (historic – future) tests (Sect. 2.4).
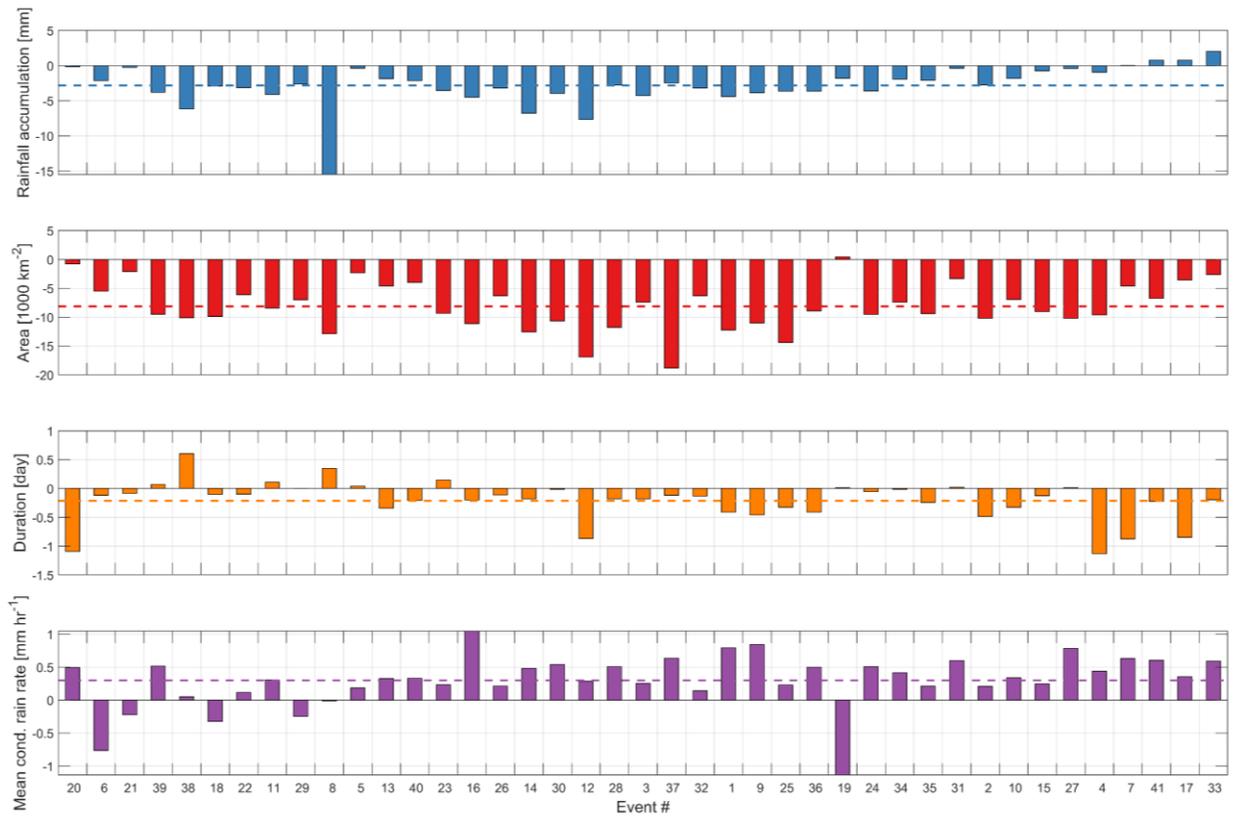

Figure S4. Change between future and historic simulations in event-average rainfall accumulation (blue), rainy area (red), event duration (orange), and mean conditional rain rate (purple), across the 41 HPEs analyzed. Events are ordered by their normalized changes in rainfall accumulation (see Fig. 5).
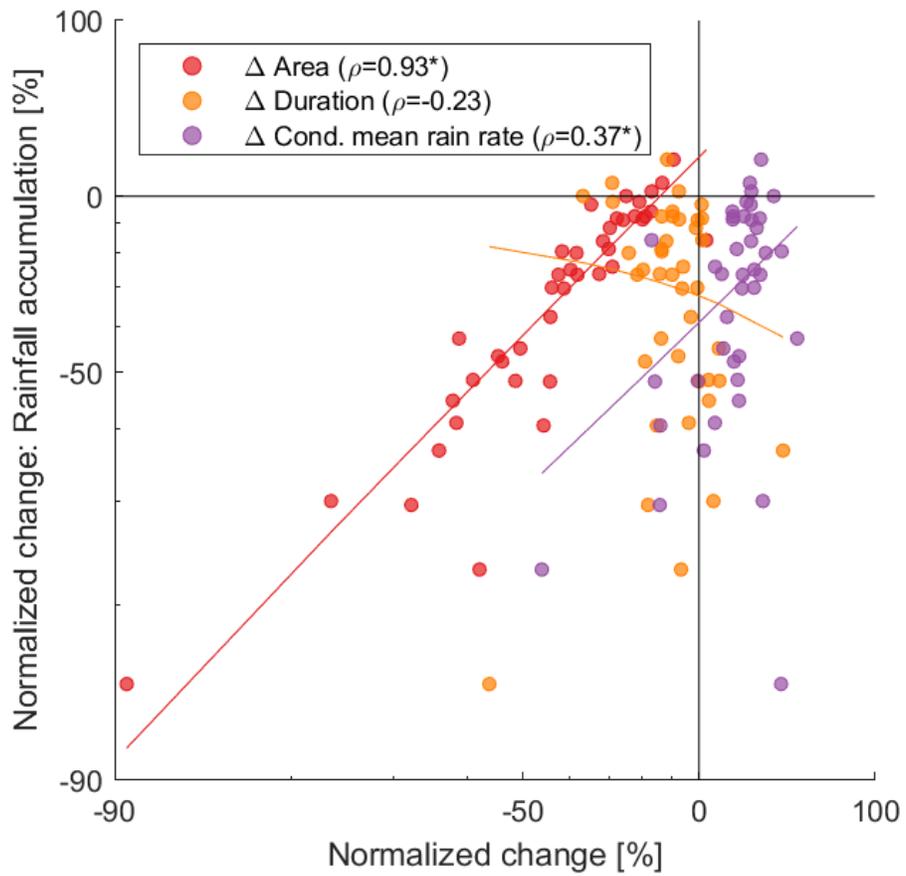

Figure S5. Association between the change in rainfall accumulation throughout the analyzed HPEs (vertical axis) and the different parameters shown in Fig. 5. Lines are the linear regressions between the parameters. Spearman's rank correlations are noted in the legend. Asterisks denote significant correlation.
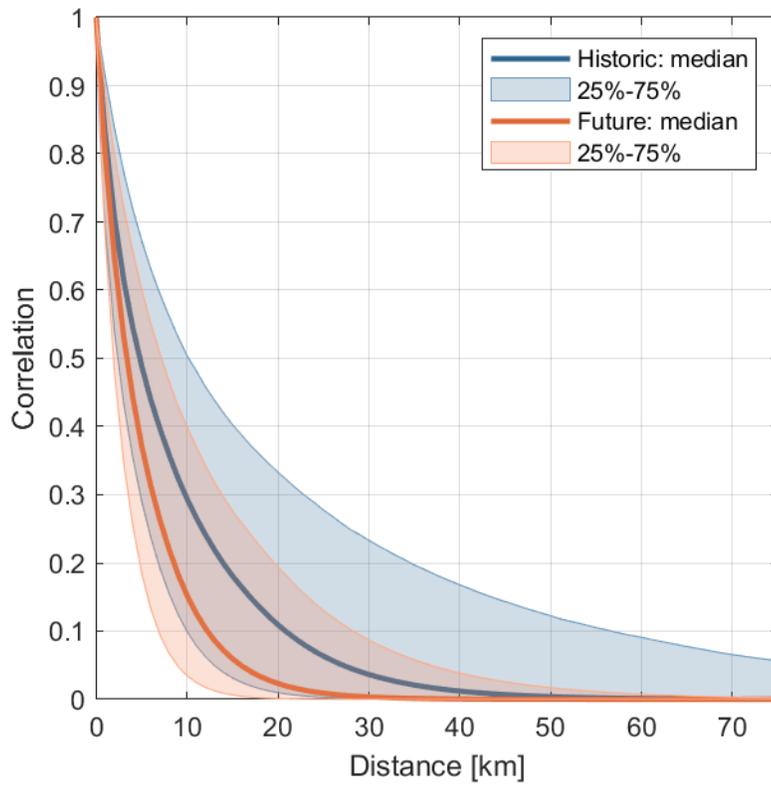

Figure S6. Spatial autocorrelation of the convective 10-min time steps for historic (blue) and future (orange) simulations. The number of convective time steps in historic and future simulations per event are 388±196 ($\mu \pm \sigma$) and 378±211, respectively. Calculations based on Marra and Morin (2018).
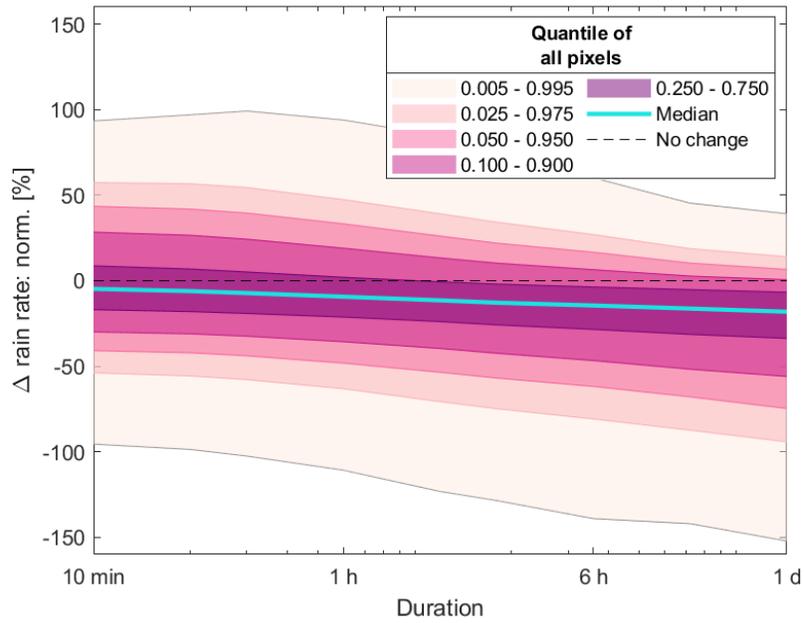

Figure S7. Quantiles among pixels (see Fig. 7) exhibiting different rain rate changes plotted versus the duration examined. Values are normalized to the areal mean value of each duration.
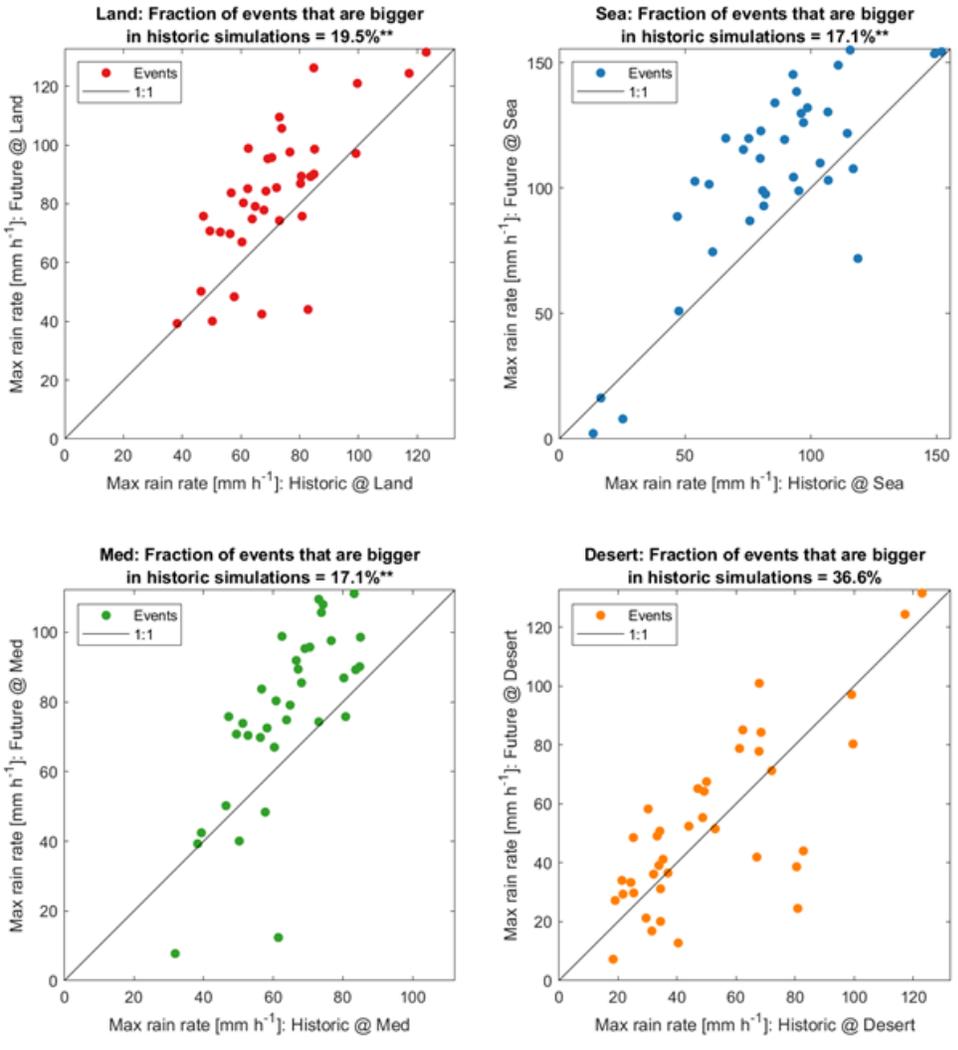

Figure S8. Same as in Fig. S3, but for maximal 10-min rain rate calculated throughout the pixels in each region and along all time steps. Maximum across all regions is in Fig. 4c.
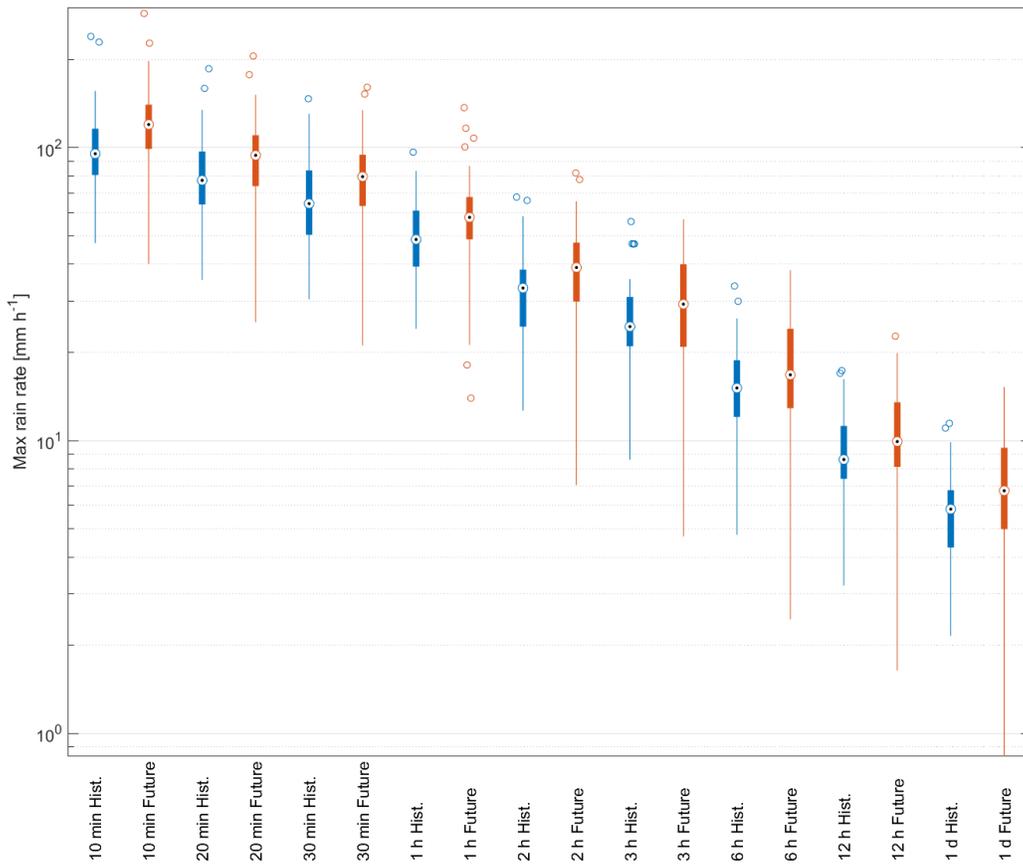

Figure S9. Boxplots of regionally maximal rain rates (across all pixels and time steps) for various durations. White circles with black dots are median values, boxes are the inter-quartile range (IQR), whiskers represents the full distribution except for cases where outliers (hollow circles) are found beyond the range of $\pm 1.5 \times IQR$ from the box.
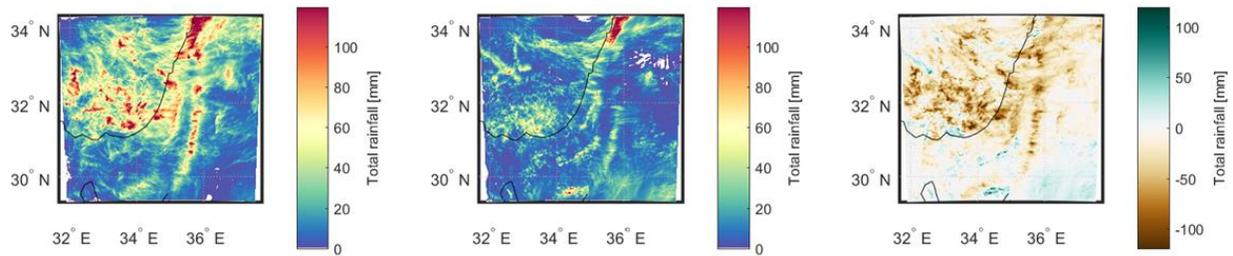

Figure S10. Rainfall in HPE#8 (1-7 Nov 1994). (a) Rainfall accumulation for the historic simulation (mean = 30.0 mm). (b) Total rainfall for the future (PGW) simulation (mean = 14.5 mm). (c) Difference between historic and future simulations (future – historic).

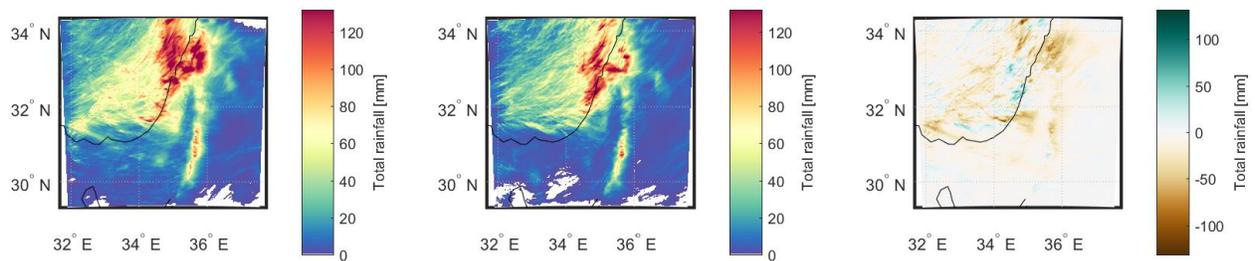

Figure S11. Same as figure S4, but for HPE#12 (4-9 Feb 1995). Historic simulation mean = 28.8 mm; future mean = 21.1 mm.

Movie S1. Animation of rain rate through time in historic (left) and future (right) simulations for HPE #1 (Table S1; Sect. 3.1).

Movie S2. Similar to Movie S1, but for HPE #8.
