8 **ABSTRACT**

9 Apatite fission track (AFT) analyses for granitoid and metamorphic bedrock samples from the
10 Western Superior Province (Ontario), the Churchill-Rae Province (Melville Peninsula and
11 Southampton Island, Nunavut), and the Slave Province (Northwest Territories) show a broad
12 range of single grain effective uranium concentrations (eU) (<1 to ~300 ppm) and some of the
13 oldest reported AFT ages in North America. Although most of our samples are characterized by
14 near-endmember fluorapatite composition with implied low track retentivity (<0.1 apfu Cl, r_{mr0}
15 ~0.85-0.82), single-grain AFT ages are statistically overdispersed and ages decrease with
16 increasing eU content. This eU-age relationship is resonant of the Hendriks and Redfield (2005)
17 *Earth Planet. Sci. Lett.* **236** (443-458) argument for α-radiation enhanced fission track annealing
18 (REA) and is analogous to the negative age-eU correlations observed in published zircon and
19 titanite (U-Th)/He data from slowly-cooled cratonic rocks. In all cases, the samples fail the
20 canonical χ^2 test (<5%), generally considered to indicate that the ages are unlikely to be drawn
21 from a single Poissonian distribution with a discrete mean value and may represent multiple
22 populations. The high intra-sample age variability for low-Cl bedrock apatites with protracted
23 histories (>200-500 m.y.) at <100°C since the Precambrian suggests strong REA control on AFT
24 ages. Conversely, some low Cl AFT samples with a narrower eU range show less age dispersion
25 and a weak apparent age-eU correlation. A complex trade-off between radiation damage,
26 chemical composition (e.g. low Cl and REE enrichment), and thermal history is implied when
27 eU and r_{mr0} are positively correlated. Previous assessments of the influence of REA on AFT age
28 were based on evaluating central age and mean track length, which potentially mask high single-
29 grain age scatter and REA effects due to the modal nature of central age determination. REA is
30 also supported by and compatible with materials science and nuclear waste studies of radiation
31 damage in different apatite groups, therefore it is crucial that bedrock samples exhibiting high
32 age scatter are evaluated in terms of intra-sample compositional heterogeneity. AFT samples
33 with relatively low Cl concentrations are especially prone to greater REA control of cooling ages
34 and this underscores the need for routine acquisition of compositional data for AFT datasets. Our
35 broad range in single-grain AFT ages (with no other clear, strong compositional controls)
36 supports the notion that radiation damage affects both the AFT and (U-Th)/He
37 thermochronometers in slowly-cooled settings and must be accounted for during thermal history
38 modeling and interpretation.

39 Keywords: apatite; fission track; alpha damage; radiation-enhanced annealing; uranium

40

1. Introduction

Uranium and thorium-rich minerals accumulate radiation damage over geological time, with the primary spontaneous decay process in apatite being ^{4}He α-particle emission during ^{238}U decay (Donelick et al., 2005 for review). The majority of radiation damage results from α-recoil in the apatite lattice, whereas fission events are a minor contribution (for every ~2 million ^{238}U nuclei undergoing α-decay only one fission event occurs, e.g. Donelick et al., 2005). The ion-spike explosion model of Fleischer et al. (1965) states that positive ions created by the transmission of highly charged fission fragments repel one another and form a cylindrical region of crystal damage. The fission track dating method is based on the accumulation of these crystallographic damage trails due to spontaneous nuclear fission in U-bearing minerals such as apatite $Ca_5(PO_4)_3(OH,F,Cl)$ (Price and Walker, 1963; Wagner, 1968; Naeser and Faul, 1969). Apatite fission track (AFT) thermochronology is established on the principle that crystal damage from fission fragments is annealed with increasing temperature, which results in a quantifiable reduction to track lengths and track density in the apatite volume (e.g. Gleadow and Duddy, 1981; Green, 1988). However, difficulties remain in fully characterizing the thermally-activated annealing behaviour of fission tracks at geologic timescales and the temperature of complete track annealing, as these factors are influenced by duration of heating (Duddy et al., 1988; Green et al., 1986; Green, 1988; Green et al., 1989), variable apatite composition (i.e. common fluorapatite vs. chlorapatite; Carlson, 1990; Barbarand et al., 2003; Carlson et al., 1999), and crystal anisotropy (e.g. Donelick et al., 1999; Ketcham et al., 2007; Nadzri et al., 2017). Chlorine content is considered the dominant compositional control (Green et al., 1986) on fission-track retentivity when >0.1 atom per formula unit, apfu or >0.35 wt.% (Barbarand et al., 2003), along with secondary Ca-site (substituting) cations, such as Fe, Na, Mn, Sr, and Mg, and some rare-earth elements (REE) such as La and Ce (Barbarand et al., 2003; Carlson et al., 1999; Ravenhurst et al., 2003). However, the trade-offs between kinetic variability, elemental substitutions, and track annealing behaviour are multifaceted and not fully understood (Barbarand et al., 2003; Ketcham et al., 1999; Ketcham et al., 2007).

The internal structure of fission tracks in apatite control the annealing process, which is very different from zircon annealing where amorphous tracks "heal" by recombination of vacancies and interstitials in the track interior (Li et al., 2010; Li et al., 2011; Li et al., 2012). Track

71 shortening in apatite occurs due to thermo-emission of vacancies from the porous track core to
72 the adjacent crystalline matrix (Li et al., 2010; Li et al., 2011) and tracks become discontinuous
73 or segmented due to Rayleigh instability, Brownian motion, or motion of track segments due to
74 the high surface energy and diffusivity of voids (Li et al., 2011). To complicate annealing
75 behaviour further, it has been well known for decades that there are small length differences
76 between spontaneous and induced tracks and that apatite FT annealing of up to 10-15% or ~1.5-
77 2.5 µm (fading) can occur at ambient temperatures over millions to billions of years (e.g.
78 Crowley et al. 1991; Donelick et al., 1990).

79

80 In contrast to fission events, α-decay damage accumulates in minerals through energetic α-
81 particle exchange by ionization and electronic excitation and by α-recoil "ballistic" collisions
82 with atomic nuclei in the mineral lattice (e.g. Ewing and Weber, 2010; Weber et al., 2015). The
83 α-recoil collisions produce more damage due to the greater destructive interaction with the
84 crystal structure (Holland and Gottfried, 1955). The accumulation of energetic particles in the
85 crystal and a high-energy absorption rate can result in self-heating from α-decay and permanent
86 structural defects can form as a result of energetic electron interactions, which produce electron-
87 hole pairs – resulting in charged defects, bond rupture, and increased defect diffusion in
88 fluorapatite (Ewing and Weber, 2010; Wang et al., 1994). Damage results in the formation of
89 point defects and defect clustering within the mineral lattice and causes a crystalline-to-
90 amorphous transition at high levels of damage (e.g. Ewing et al., 2000; Ewing and Weber, 2010;
91 Weber et al., 2012). The primary α-radiation damage mechanisms include the "direct impact"
92 and "defect accumulation" models (Ewing et al., 2000 and refs. therein). The direct impact
93 model (e.g. Gibbons 1972; Morehead and Crowder, 1972) is predicated on the assumption that
94 an amorphous (non-crystalline) region is formed within the core of a displacement cascade, and
95 complete amorphization is reached when the amorphous domains increase with ion dose,
96 eventually occupying the entire sample. The point defect accumulation model (e.g. Gibbons
97 1972; Jackson 1988) assumes that emitted particles create discrete point defects and that
98 amorphization is achieved when the local defect concentration reaches a critical level. For
99 example, the α-decay of U and Th in natural apatites containing REE and Si leads to a
100 crystalline-to-amorphous "metamict" change due to radiation damage accumulation – contingent

101 upon composition, crystalline structure, irradiation level, and temperature (Weber et al., 1997).
102 The general view is that at low temperatures, typical phosphate apatite compositions require less
103 radiation to become amorphized than silicate apatites (e.g. Wang et al., 1994; Weber et al.,
104 1997). Durango fluorapatite ($Ca_{10}(PO_4)_6F_2$) becomes amorphized at lower temperatures and at
105 lower radiation dose than silicate-apatite ($Ca_2La_8(SiO_4)_6O_2$), however at temperatures $\geq 77°C$,
106 fluorapatite required 5x higher dose to become amorphous than silicate apatite (Wang et al.,
107 1994). The critical temperature for amorphization varies depending on the irradiation dose
108 (Ewing et al., 2000), however apatite composition and temperature directly play a role in the
109 persistence of α-radiation damage and the example of increased silica content shows a reduction
110 in the recrystallization tendency of apatite (Ewing et al., 2000). This raises the question of
111 whether and how (other) unusual elemental substitutions known to affect apatite retentivity (e.g.
112 Carlson et al., 1999; Gautheron et al., 2013; Djimbi et al., 2015; Ravenhurst et al., 2003) coupled
113 with slow cooling (≤ 1-$3°C$) and minor, episodic thermal annealing events over billion year
114 timescales play a role in modulating bulk radiation damage accumulation, annealing, and
115 recrystallization in apatite.

116

117 Radiation damage has implications for multiple diffusion-based thermochronometers, and even
118 though fission track dating is established on constraining crystalline damage, the suspected
119 effects of α-damage on track annealing have been controversial (e.g. Hendriks and Redfield,
120 2005). A drawback of fission-track dating with respect to visualizing damage is that the process
121 of increasing the optical visibility of tracks requires chemical etching, which erases the initial
122 damage structure and essential information about the physical scale of radiation damage (Afra et
123 al., 2011). Ion tracks are similar in character to fission tracks (Rabone et al., 2008) and ion track
124 annealing experiments from swift heavy ion bombardment in apatite verify unit-cell increases
125 during irradiation, crystal strain and cracking at high ion fluence, high-pressure reduction of
126 amorphization, radiation-enhanced diffusion, and anisotropic lattice damage response (e.g. Liu et
127 al., 2008; Miro et al., 2005; Miro et al., 2012; Weikusat et al., 2011). Latent ion particle tracks in
128 Durango apatite were found to anneal via a two-stage process of structural relaxation followed
129 by recrystallization (Afra et al., 2011), which has also been observed in silicate apatite (Bae et
130 al., 2007). Ionization-annealing of ballistic damage in SiC revealed a surprisingly low threshold

131   for electronic energy loss (a few MeVs) to initiate annealing at room temperature and repair

132   defect clusters, crystalline structure, and displacements at the atomic level (Zhang et al., 2015).

133   Carpéna (1998) proposed that annealing in low-temperature conditions is also possible for

134   silicate apatite (fluorbritholite) with lanthanide enrichment (e.g. La, Ce) or cation substitutions

135   such as Na, Mg, Sr, Mn, Fe, U, and Th.

136

137   Radiation damage is often discussed in terms of "alpha dose," which is a quantitative estimate of

138   the self-irradiation (driven by the α-fluence) in a mineral from time-integrated damage

139   accumulation (e.g. Nasdala et al., 2001). The first-order control on α-damage is U content, or

140   "effective U" concentration (eU=U+0.235×Th+0.0046×Sm; Gastil et al., 1967) of the host grain

141   weighted for parent α-productivity. Extreme α-damage levels cause crystallographic

142   amorphization in zircon due to relatively high U content (Chakoumakos et al., 1987; Murakami

143   et al., 1991; Nasdala et al., 2001), whereas α-damage is more easily recoverable in apatite

144   (Weber et al., 1997; Li et al., 2017). (U-Th)/He dating of zircon is an excellent example of a

145   mineral demonstrating a relationship between diffusivity and α-dose/eU. The expectation is that

146   a positive age-eU correlation exists at low dose and a negative relationship is evident after the

147   damage percolation threshold (or point at which damage interconnects) is reached, causing

148   increased diffusivity (Guenthner et al., 2013). There is an expected decrease in ^{4}He diffusivity at

149   the α-recoil percolation dose of ~2.5-3.1×10^{16} α/g and then an increase in diffusivity at fission

150   track percolation achieved at a higher damage level of ~1.9×10^{18} α/g (Ketcham et al., 2013). The

151   zircon radiation damage and accumulation model (ZRDAAM; Guenthner et al., 2013) predicts a

152   complex diffusive relationship between damage accumulation/annealing (eU) and derived He

153   age that is strongly influenced by thermal history. Self-irradiation over geological timescales

154   results in high α-doses above the percolation point and a negative age-eU relationship should

155   become apparent in grains that have accumulated high radiation damage and spent significant

156   time below the He partial retention zone. This age-eU pattern is achieved either through He loss

157   at low temperatures or alternatively, rocks spending considerable time at low temperatures and

158   experiencing a thermal pulse during their history (Guenthner et al., 2013). The model for zircon

159   radiation damage has been recently improved upon to show that bulk radiation damage annealing

160   requires longer durations and higher temperatures than fission track annealing, and when fission

tracks are fully annealed, the total radiation damage has only been annealed ~30-50% (Ginster et al., 2019). Fission track annealing characteristics between zircon and apatite are different (Li et al., 2011), but α-recoil damage is known to diminish fission track thermal stability in U-bearing phases such as zircon (Garver et al., 2004; Kasuya and Naeser, 1988), titanite (Lumpkin et al., 1991), and apatite (Carpéna and Lacout, 2010; Ritter and Märk, 1986). These findings imply that the presence of α-damage lowers the stability of fission tracks in minerals commonly used in thermochronology and that α-damage can persist above temperatures typically believed to completely anneal fission damage.

The apatite (U-Th)/He (AHe) thermochronometer is affected by radiation damage (e.g. Shuster et al., 2006; Shuster and Farley, 2009). There are consequences for He diffusion in a damaged mineral lattice, with the main assertion being that radiation-induced damage impedes helium diffusivity and that damage evolves as a function of temperature and eU concentration (e.g. Farley, 2000; Flowers et al., 2009; Gautheron et al., 2009; Ketcham et al., 2017; Recanati et al., 2017; Shuster et al., 2006; Shuster and Farley, 2009). Radiation damage effects on He retentivity have been explored and described through models of diffusive loss (Shuster et al., 2006; Flowers et al., 2009; Gautheron et al., 2009; Gerin et al., 2017; Willett et al., 2017). There is now a better understanding of the numerous factors affecting He diffusivity in apatite including compositional and crystallographic controls on α-damage annealing (Djimbi et al., 2015; Gautheron et al., 2013; Gautheron et al., 2009), crystallographic microvoids (Zeitler et al., 2017), vacancy damage (Gerin et al., 2017), and strain-induced dislocation traps (McDannell et al., 2018b). The α-damage recoil track percolation threshold has been recently described for He diffusivity in apatite (Ketcham et al., 2017; Recanati et al., 2017), and seems genetically similar to damage modes in zircon. A similar age-α-dose relationship has been observed for titanite (Baughman et al., 2017; Guenthner et al., 2017), however a titanite radiation damage model has yet to be formally described. Due to the difficulty in direct damage observation in past studies and in determining α-recoil kinetics, α-damage annealing in apatite has long been considered analogous to fission track annealing behaviour, and the most commonly used empirical diffusion models of damage accumulation and annealing are established on this principle (Flowers et al., 2009; Gautheron et al., 2009). However, it has been previously proposed that the rate of α-damage annealing is slower than fission-track annealing (e.g. Ritter and Märk, 1986), which would

192 require revision of existing models. The dilemma is that we really do not know what the kinetics

193 are for α-damage annealing, and most importantly in this context, we should not assume that it is

194 the same for both damage types. We have done so for the purposes of trying to model damage

195 effects on He diffusion in apatite, but with arguably limited success especially in geologic

196 settings where the kinetics for each damage mode diverge.

197

198 The developments in understanding how α-damage acts to modify He diffusion are integral for

199 using apatite as a viable thermochronometer and undoubtedly have implications for AFT analysis

200 and fission-track retention in rocks that have experienced slowly-cooled histories. The relatively

201 subtle kinetic and compositional controls on apatite annealing and retentivity in rapidly-cooled

202 settings become more complex and magnified in cratonic interiors due to their protracted thermal

203 histories at low temperatures (e.g. Green and Duddy, 2006; Flowers, 2009). There have been

204 many problems associated with the interpretation of both AFT and AHe data in slowly-cooled

205 settings, including significant intra- and inter-sample age dispersion (e.g. Fitzgerald et al., 2006;

206 McKeon, 2012; McDannell et al., 2018b) and AFT<AHe cooling age inversion (e.g. Hendriks

207 and Redfield, 2005; Green et al., 2006; Flowers and Kelley, 2011). Hendriks and Redfield (2005)

208 suggested that elevated U concentration in apatite has a strong influence on fission-track

209 annealing, invalidating prior thermochronologic interpretations for cooling signals across the

210 Fennoscandian Shield. In a series of papers, this matter and the robustness of AFT versus AHe

211 dating was debated (Green and Duddy, 2006; Hendriks and Redfield, 2006; Larson et al., 2006).

212 Hendriks and Redfield's argument for AHe dates being more reliable than AFT ages was

213 contested and attributed to variability in He retentivity, rather than variability in AFT annealing

214 behaviour (Green et al., 2006). The apparent U control on AFT ages was instead attributed to

215 lithologic differences and elevated Cl content for the analysed apatites (Kohn et al., 2009).

216

217 The effect of U on AFT ages was perhaps dismissed prematurely, and analytical advances in the

218 past 15 years have motivated changes in AFT methodology to better address this problem. The

219 potential relationship between U and AFT age has long been recognized and an early example of

220 a negative correlation between zircon FT age and U concentration was given in Carter (1990)

221 using the external detector method (EDM). Discussion around this relationship focused on

single-grain U variability, track density, and potential counting biases, as well as the fact that both AFT age and U estimates are derived from the same induced track count, and therefore related. The recommendation in Carter (1990) for determining if a real association exists between age and U is to measure U independently. The introduction of laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) for AFT dating (Hasebe et al., 2004) made the direct measurement of U procedurally advantageous over the EDM, which uses an irradiated, low-U muscovite detector as a proxy for apatite ^{238}U content through reactor-induced fission. The main drawback for ICP-MS ^{238}U measurement is that very low U content (<< 0.5 ppm) is difficult to measure and leads to modestly older ages compared to the EDM (Seiler et al., 2013), nonetheless U can still be reliably measured at <1 ppm. It is also well established that apatites with high fission-track density (i.e. old grains or high U) are more difficult to measure using the EDM, consequently biasing AFT measurements towards younger or low U grains (e.g. Carter, 1990; Seiler et al., 2013). In a series of analyses on laboratory age standard AFT grains, Hasebe et al. (2004) showed that the EDM underestimated the U content of high U, whole-grain laboratory age standard apatites with respect to LA-ICP-MS measurements.

In light of advances in precise, *in situ* U concentration measurements for AFT analysis, re-evaluation of α-radiation enhanced annealing (REA) is warranted. Assessing the viability of REA in slowly-cooled terranes is important for the understanding of the annealing kinetics of apatite fission tracks and the implications for other thermochronometers that are affected by the same α-damage and annealing processes, such as the case with the apatite (U-Th)/He system (Gautheron et al., 2013; Gautheron et al., 2009; Recanati et al., 2017; Shuster et al., 2006). We present new LA-ICP-MS AFT data from Archean-Paleoproterozoic plutonic granitoids and gneissic bedrock samples from localities across the Canadian Shield and assess the REA potential related to U content. In general, grains that are characterized by highly variable eU and low Cl concentrations (<0.1 apfu) typically show a strong, negative age-eU correlation, whereas contrasting metasedimentary samples from southern Baffin Island with "typical apatite" eU levels (less variability, ~20-30 ppm) and low Cl (<0.1 apfu) show seemingly weak U control on age, less single-grain age scatter, or display complex relationships between retentivity proxies (i.e. eU and r_{mr0}).

253 Our intent is not aimed at generating a calibrated model of REA behaviour, nor wholly
254 reconciling observations between AFT and AHe single-grain ages in slowly-cooled settings for
255 geologic interpretation – but rather to bring REA back into the communal foreground and assert
256 that this phenomenon exists, although it is poorly understood due to complexities associated with
257 fission-track annealing.

258

2. Regional Geologic Setting

260 The AFT samples presented here all come from exposed Precambrian granitic and gneissic
261 bedrock across Canada. An overview of the Precambrian geologic history of the Canadian Shield
262 is provided by Hoffman et al. (1989) and here we focus mainly on areas of Archean (>2.5 Ga)
263 crust that are currently exposed across the Canadian interior that were sutured during Trans-
264 Hudson orogenesis and Laurentia assembly at ca. 1.9-1.8 Ga. The major terranes that were
265 sampled are the Western Superior Province (Percival et al., 2012), rocks of the northeastern
266 Churchill Province-Rae domain at Southampton Island (Berman et al., 2013) and Melville
267 Peninsula (Berman et al., 2015), and the Slave Province (Isachsen and Bowring, 1994) all shown
268 on figure 1. Results from southern Baffin Island are also shown for comparison to the
269 aforementioned data (see discussion).

270 The Archean-Proterozoic tectonomorphic history and setting for each terrane is thoroughly
271 described in their respective reference. All of these regions have presumably been exposed at
272 near surface conditions or in the upper crust since the late Proterozoic and experienced minor,
273 episodic burial throughout the Phanerozoic (Burgess, 2008; Miall and Blakey, 2008). The
274 Archean-Paleoproterozoic age of these terranes and the limited Phanerozoic sedimentary strata
275 provide few constraints on the burial and exhumation history of these rocks. The Phanerozoic
276 sedimentary succession in central Canada is preserved in Hudson Bay (mainly Paleozoic, ~2500
277 m thick; fig. 1) and unconformably overlies Canadian Shield bedrock (Pinet et al., 2013). The
278 Paleozoic platform sequence is exposed in the Western Superior Province at Hudson and James
279 Bay, and Ordovician-Silurian sediments onlap much of the southern Arctic, northern Melville
280 Peninsula (Corrigan et al., 2013), and Baffin Island crystalline bedrock (fig. 1).

281

282   In the absence of formal models for the time-temperature history of many of these areas,
283   geologic evidence and the sparse Phanerozoic sedimentary record yield clues about the thermal
284   history experienced by Shield rocks. Kimberlites can include sedimentary xenolith evidence of
285   the pre-existing Paleozoic cover that was removed by erosion. The Jericho kimberlites in the
286   central Slave craton have limestone xenoliths of Middle Devonian age (L. Eifelian-E. Givetian)
287   (Cookenboo et al., 1998) and the ca. 75-45 Ma Lac de Gras kimberlite field suggests up to ~1.4
288   km of Cretaceous strata existed at that time (Nassichuk and McIntyre, 1995; Stasiuk et al., 2006).
289   The Mesozoic Kirkland Lake (Ontario) kimberlites contain Ordovician-Devonian xenoliths in
290   the Superior Province (McCracken et al., 2000) and the Jurassic Chidliak kimberlites of southern
291   Baffin Island also contain Late Ordovician-Early Silurian xenoliths (Zhang and Pell, 2014).
292   These areas all indicate that most of interior Canada was inundated by a shallow sea in the
293   middle Paleozoic and experienced some level of regionally cohesive burial and exhumation
294   through Paleozoic-Mesozoic time, which is reinforced by regional studies using low-temperature
295   thermochronology (Ault et al., 2009; Ault et al., 2013; Feinstein et al., 2009; Kohn et al., 2005).
296   AFT studies suggest that most of the Trans-Hudson region remained at <80-90°C since the
297   Ordovician (Pinet et al. 2016) and that rocks of the Superior Province in Ontario were never
298   hotter than ~90°C during episodic burial and exhumation since the Cambrian (Kohn et al., 2005).
299   Generally speaking, the majority of the Canadian Shield has been at temperatures <100-120°C at
300   least since the latest Precambrian-Cambrian (~600-500 Ma).

301   **3. Analytical Methods**

302   *3.1 LA-ICP-MS apatite fission track analysis*

303   AFT ages were determined using the LA-ICP-MS method (Hasebe et al. 2004; Donelick et al.
304   2005; Chew and Donelick 2012), which gives similar results to the traditional external detector
305   method but avoids the requirement for sample irradiation in a nuclear reactor (e.g. Seiler et al.,
306   2013). A single grain mount was used to acquire AFT age, length, and D_{par} data for each sample
307   according to the procedures described in Donelick et al. (2005). Following mineral separation
308   procedures, apatite separates were mounted in epoxy, polished, and etched in 5.5M HNO_3 for
309   20s at 21°C to reveal all natural fission tracks intersecting the polished grain surface. For each
310   age grain, locations were recorded and spontaneous AFT densities were counted using a
311   microscope at 2000x magnification under unpolarized light. ^{238}U concentrations were determined

312 for the track count areas on each age grain using the Washington State University (WSU)

313 Finnigan Element II Magnetic Sector ICP-MS by measuring the weighted mean ratio of ^{238}U to

314 ^{43}Ca from multiple spot analyses at a fixed laser point (^{232}Th and ^{147}Sm were also measured).

315 The volume of ablated material is estimated using ^{43}Ca, assuming that Ca occurs in

316 stoichiometric amounts. AFT ages were calculated using the LA-ICP-MS ζ-calibration approach

317 (Donelick et al., 2005; Vermeesch, 2017) based on the Durango apatite age standard. Apatite U-

318 Pb age data were acquired for AFT age grains as described in Chew and Donelick (2012).

319 Apatite U-Pb age density plots were created using DensityPlotter v. 8.2 software (Vermeesch,

320 2012) using a Kernel Density Estimator with an adaptive bandwidth and logarithmic

321 transformation of the single-grain common Pb-corrected isotopic sum ages and their 2σ errors.

322 The quoted "mixture model" ages (table 1) incorporate all measured isotopic sum ages and are

323 for a single age population.

3.2 Apatite elemental analyses and the "effective" Cl kinetic parameter

325 Sample apatite grains were analysed for 13 elements (F, Na, Mg, P, S, Cl, Ca, Mn, Fe, Sr, Y, La,

326 and Ce) by electron probe microanalysis (EPMA) at the Washington State University Peter

327 Hooper Geoanalytical Laboratory using a JEOL JXA8500F Field Emission Electron Microprobe

328 operated at 15 kV (20 nA current) with a beam size of 5 μm. Laboratory weight % oxide values

329 were converted to atom per formula unit (apfu) values, including estimation of OH content from

330 Cl and F values, using the apatite stoichiometric model of Ketcham (2015). The r_{mr0} kinetic

331 parameter was calculated for each analysed apatite grain by substituting the apfu values into the

332 multivariate equation of Carlson et al. (1999). The nonlinear r_{mr0} values were converted into

333 "effective" Cl (eCl) values (in apfu) using the empirical r_{mr0}-Cl relation of Ketcham et al. (1999)

334 for better visualization of data on a linear scale, for calculating arithmetic means of single-grain

335 kinetic parameters, and for comparison with the commonly used measured Cl kinetic parameter.

336 D_{par} (mean etch pit diameter perpendicular to c-axis; e.g. Donelick et al., 2005) data are not

337 discussed in detail here. However, D_{par} has been found to be a lower precision kinetic proxy

338 when compared to r_{mr0} or measured Cl (Issler et al., 2018), and in other localities across Canada

339 it has demonstrated limited utility in successfully separating apatite grain age populations (e.g.

340 Issler and Grist, 2008; McDannell et al., 2019; Powell et al., 2017; Schneider and Issler, 2019).

341 In the majority of our samples, measured Cl and D_{par} show no relation with AFT age and in

342   general, eCl is preferred as a kinetic parameter over measured Cl because it takes into account

343   the contribution of multiple elements that influence track retentivity (e.g. Barbarand et al., 2003;

344   Carlson et al., 1999). Negative eCl values (r_{mr0} > 0.84) indicate that AFT track retentivity is

345   lower than that of the apatite used for the laboratory annealing experiments (Ketcham et al.,

346   1999). We use the Carlson et al. (1999) r_{mr0} equation rather than the Ketcham et al. (2007)

347   equation because in our experience with multi-kinetic AFT populations the former generally

348   produces a broader range of r_{mr0} values than the latter equation for apatites displaying a range of

349   kinetic behavior. The greater spread in values can result in better discrimination between kinetic

350   age populations. Ketcham et al. (2007) demonstrates that both experimental datasets can be

351   reconciled but this does not necessarily mean that the latter equation is superior. Refitting of the

352   model parameters in the newer equation may be influenced by: (1) the narrower compositional

353   range of the Barbarand et al. (2003) experimental apatite compared with those of Carlson et al.

354   (1999), which may be biasing the fit due to the overriding influence of Cl and (2) there may be

355   residual analyst bias between experiments even after corrections were applied.

356

357   **4. Apatite fission track results**

358   We present new LA-ICP-MS AFT results for 12 samples taken from cratonic crystalline bedrock

359   across the Canadian interior (table 1; refer to the Supporting Information [SI] for all raw

360   analytical data). Two other new samples from Baffin Island are not from crystalline bedrock, but

361   are from Paleoproterozoic metasediments overlying Archean basement that have internally

362   consistent apatite U-Pb ages and are treated as homogeneous samples. The Baffin Island AFT,

363   apatite U-Pb, and EPMA datasets (McDannell et al., 2018a) are available from

364   http://dx.doi.org/10.1594/IEDA/111241. There is also an additional AFT sample with

365   accompanying AHe data previously published for the Hudson Bay region in Pinet et al. (2016)

366   that is examined in the discussion (see table 1). Published AFT data from Canada and other areas

367   worldwide are included for comparison only to illustrate other types of complex relationships

368   between AFT single-grain age, eU/α-dose, and other kinetic parameters (see discussion). We

369   want to emphasize that this dataset is complex, and in specific cases this complexity may

370   preclude thermal history interpretation (at this time) without a proper understanding of the

371   kinetics governing REA or at the very least, differences between fission track and α-damage

372   annealing rates. However, we discuss some possible ways forward when dealing with AFT and

373   accompanying elemental data from slowly-cooled terranes, which may serve as a framework to

374   assist in future interpretation.

375

376   A plot of central AFT age/MTL versus eU is shown in figure 2A, B. This visualization of AFT

377   data (generally utilizing ^{238}U only) has been the convention for previous studies addressing REA

378   (e.g. Hendriks and Redfield, 2005; Kohn et al., 2009). However, central age plots are non-ideal

379   for displaying age-eU relationships because of the modal tendency of this metric, which masks

380   high age scatter between individual grains. In our case there is large geographic distance between

381   sample locations and discrete thermal histories should be expected for each sample, yet there is a

382   consistent decrease in age with increasing eU. Our apatites are relatively mono-compositional.

383   Apatites characterized by >0.35 wt. % Cl (>0.1 apfu) are considered structurally controlled by Cl

384   and imply higher fission track retentivity (Barbarand et al., 2003), whereas our data are almost

385   entirely low retentivity F-apatite (fig. 2C) or from apatite varieties with greater hydroxyl and Ca-

386   site cation substituents (e.g. REE-rich F-apatite) There is also the possibility that a very minor

387   apatite component (<10 grains total) is in the belovite or britholite groups based on wt. % P_2O_5

388   (Pan and Fleet, 2002). Radial plots are useful for assessing mixtures of single-grain ages and

389   AFT age precision (Galbraith, 1990). All of our samples fail the χ^2 test when plotted on radial

390   plots, indicative of high age dispersion (fig. 3). Detrital AFT data often fail the χ^2 test due to

391   variable provenance (and composition), however for slowly-cooled bedrock samples failure may

392   be expected, d□□□□□ the range of single grain kinetic responses to annealing under slow-

393   cooling conditions (Galbraith and Laslett, 1993). An interesting feature of these data overall are

394   that samples with fewer grains typically have much lower dispersion (fig. 3), which is probably a

395   result of "under-sampling" and is an issue that may be unwittingly pervasive in older vintage

396   AFT datasets from slowly-cooled terrains.

397

398   Fission track length distributions for each sample are shown in figure 4, and in the absence of

399   thermal modeling, can be qualitatively assessed to understand thermal history complexity to first

400   order. Length distributions are presented as frequency (%) in 1 μm bins with equivalent normal

401   distributions shown for the mean ± 1σ (solid, blue curve) and the mode (dashed, red curve). The

track length distributions are mostly unimodal and shortened (centered at ~12-13 µm), signifying monotonic slow cooling or slow cooling and reheating (partial annealing) to ~65-80°C (Gleadow et al., 1986). Bimodal distributions, skewed distributions, or those with 'shoulders' can signify single-phase reheating to higher temperatures of ~80-100°C or episodic reheating in the partial annealing zone (~60-110°C; Gleadow et al., 1986). Baffin Island sample 09SRB-M100 and Melville Peninsula sample SNB-01-M2055 are examples that exhibit "out-of-phase" mean and mode distributions (fig. 4), which is indicative of bimodality and implies multi-stage thermal histories (ignoring differences in *n* tracks). These areas are both characterized by geologic and thermochronologic evidence of Paleozoic and/or Mesozoic burial (McDannell et al., 2019; Pinet et al., 2016).

We discuss the geologic context and other relevant high-temperature dating performed on each sample (when applicable) for each Canadian AFT sample below. All samples have summarized AFT information in the text and table 1. Likewise, all published samples are presented and discussed with known information relevant to their histories.

4.1 Western Superior Province

Sample PBA-98-743 is from a biotite tonalite-gneiss in the Harmon Lake Gneiss Complex of the Wabigoon Subprovince. The gneiss has a mean ^{207}Pb/^{206}Pb zircon core metamorphic protolith age of 2890 ± 8 Ma (MSWD=1.1) and a U-Pb titanite age of 2678 ± 2 Ma (Percival et al., 2004). The corresponding sample apatite U-Pb mixture model single age peak is 2971 ± 174 Ma (2σ; n=25). The AFT sample has a pooled age of 572.3 ± 15.6 Ma (1σ; n=40) and a central age of 597 ± 37 (1σ) with 36% age dispersion. The mean track length (MTL) is 12.07 ± 1.94 µm (1σ; n=130). The mean kinetic parameters for PBA-98-743 are: measured D_{par} of 1.89 µm, eU of 7 ppm (range 1-19 ppm), calculated r_{mr0} of 0.84, and measured Cl of 0.008 apfu.

Sample 03-GRS-013 is from a tonalite-quartz diorite in the Mesoarchean Sachigo Subprovince. The apatite U-Pb mixture model single age peak is 3009 ± 94 Ma (2σ; n=29). The AFT sample has a pooled age of 414.0 ± 14.1 Ma (1σ; n=40) and a central age of 447 ± 34 (1σ) with 46% age dispersion. The MTL is 12.51 ± 1.63 µm (1σ; n=131). The mean kinetic parameters for 03-GRS-

430 013 are: measured D_{par} of 1.91 µm, eU of 33 ppm (range 1-241 ppm), calculated r_{mr0} of 0.84, and

431 measured Cl of 0.003 apfu.

4.2 Slave Province

433 *Sample 12-DRA03-001* is from a plagioclase-bearing porphyritic intrusion with a turbidite

434 deposit near Wheeler Lake in the Northwest Territories. This sample is at the approximate

435 location of the Isachsen and Bowring (1994) lithic tuff sample (within turbidites) that has a

436 reported U-Pb zircon age of 2612 ± 1 Ma. The sample apatite U-Pb mixture model single age

437 peak is 2628 ± 96 Ma (2σ; n=36). The AFT sample has a pooled age of 335.7 ± 11.3 Ma (1σ;

438 n=40) and a central age of 344 ± 14 (1σ) with 22% age dispersion. The MTL is 12.04 ± 2.39 µm

439 (1σ; n=131). The mean kinetic parameters for 12-DRA03-001 are: measured D_{par} of 1.87 µm, eU

440 of 16 ppm (range 2-55 ppm), calculated r_{mr0} of 0.83, and measured Cl of 0.019 apfu.

441 *Sample BNB97-035* is plutonic med-coarse grained biotite granitoid with strong lineations taken

442 from the west flank of the Sleepy Dragon Complex in the Yellowknife Domain of the Slave

443 craton with nearby basement crystallization ages of ca. 2900 Ma (Bleeker et al., 1999), similar to

444 the sample apatite U-Pb mixture model single age peak of 2858 ± 124 Ma (2σ; n=22). The AFT

445 sample has a pooled age of 229.3 ± 22.1 Ma (1σ; n=40) and a central age of 272 ± 16 (1σ) with

446 34% age dispersion. The MTL is 12.75 ± 1.80 µm (1σ; n=116). The mean kinetic parameters for

447 BNB97-035 are: measured Dpar of 1.72 µm, eU of 21 ppm (range 0.2-98), calculated r_{mr0} of

448 0.85, and measured Cl of 0.006 apfu.

449 *Sample 12NK-L18A3* is from granitic gneiss in Nunavut with a zircon U-Pb age of 2487 ± 5.4

450 Ma and a metamorphic overprint U-Pb age of 2377 ± 3.5 Ma (Davis et al., 2014). The apatite U-

451 Pb mixture model single age peak is significantly younger at 1788 ± 40 Ma (2σ; n=24). The AFT

452 sample has a pooled age of 392.4 ± 9.0 Ma (1σ; n=26) and a central age of 397 ± 13 (1σ) with

453 14% age dispersion. The MTL is 11.91 ± 2.06 µm (1σ; n=78). The mean kinetic parameters for

454 12NK-L18A3 are: measured Dpar of 1.85 µm, very high eU of 339 ppm (range 139-655),

455 calculated r_{mr0} of 0.79, and measured Cl of 0.012 apfu.

4.3 Churchill-Rae Province, Melville Peninsula region

457 *Sample SNB-01-M2055* is from Melville Peninsula, ~150 km southwest of Committee Bay and is

458 a foliated biotite tonalite that cuts a komatiite at the base of the Howling Wolf section with an U-

459   Pb zircon igneous crystallization age of 2606 ± 4 Ma (Cairns et al., 2005). The apatite U-Pb

460   mixture model single age peak is 1940 ± 68 Ma (2σ; n=26). The AFT sample has a pooled age of

461   348.5 ± 9.8 Ma (1σ; n=30) and a central age of 356 ± 18 (1σ) with 24% age dispersion. The

462   MTL is 12.19 ± 2.30 μm (1σ; n=130). The mean kinetic parameters for SNB-01-M2055 are:

463   measured D_{par} of 2.00 μm, eU of 14 ppm (range 0.2-46 ppm), calculated r_{mr0} of 0.84, and

464   measured Cl of 0.003 apfu.

465   *Sample 10CXAD-086A* is from eastern Melville Peninsula on the Foxe Basin margin and was

466   collected from a plutonic gabbro-anorthosite with nearby detrital U-Pb ages of 1899 ± 7 Ma and

467   1897 ± 15 Ma in the overlying Paleoproterozoic Penrhyn Group (Partin et al., 2014). The sample

468   apatite U-Pb mixture model single age peak is 1803 ± 73 Ma (2σ; n=24). The AFT sample has a

469   pooled age of 363.1 ± 28.5 Ma (1σ; n=40) and a central age of 460 ± 44 (1σ) with 57% age

470   dispersion. The MTL is 12.60 ± 1.79 μm (1σ; n=132). The mean kinetic parameters for

471   10CXAD-086A are: measured D_{par} of 2.12 μm, eU of 13 ppm (range 0.2-73 ppm), calculated r_{mr0}

472   of 0.82, and measured Cl of 0.029 apfu.

473   *Sample 11CXAN017* is from the Prince Albert block on Melville Peninsula and was collected

474   from a Neoarchean Bt-Kfs porphyritic monzogranite. The sample apatite U-Pb mixture model

475   single age peak is 1676 ± 59 Ma (2σ; n=18). The AFT sample has a pooled age of 418 ± 11 Ma

476   (1σ; n=18) and a central age of 452 ± 31 (1σ) with 28% age dispersion. The MTL is 12.67 ± 1.92

477   μm (1σ; n=120). The mean kinetic parameters for 11CXAN017 are: measured D_{par} of 1.95 μm,

478   eU of 21 ppm (range 3-43 ppm), calculated r_{mr0} of 0.85, and measured Cl of 0.002 apfu.

479   *Sample 13LVA04* is from a gabbro at the Discovery outcrop that cuts a banded iron formation

480   and the Sam Fm. at the Thelon Basin in S. Nunavut. The apatite U-Pb mixture model single age

481   peak is 2224 ± 125 Ma (2σ; n=39). The AFT sample has a pooled age of 546.0 ± 33.8 Ma (1σ;

482   n=40) and a central age of 557 ± 31 (1σ) with 21% age dispersion. The MTL is 12.44 ± 2.06 μm

483   (1σ; n=121). The mean kinetic parameters for 13LVA04 are: measured D_{par} of 1.92 μm, eU of 7

484   ppm (range 3-42 ppm), calculated r_{mr0} of 0.80, and measured Cl of 0.012 apfu.

485   *Sample 09SZ-23-01* is from Precambrian granitic gneiss at the northern margin of Melville

486   Peninsula at the Fury and Hecla Strait, <200 m from the Paleozoic unconformity presented in

487   Pinet et al. (2016). The AFT sample has a pooled age of 462.7 ± 29.9 Ma and a central age of

488   486 ± 27 Ma with 21% age dispersion. The MTL is 12.18 ± 1.58 μm (1σ; n=100). The mean

489   kinetic parameters for 09SZ-23-01 are: measured D_{par} of 1.67 μm, ^{238}U of 6 ppm (range 3-12

490   ppm), calculated r_{mr0} of 0.85, and measured Cl of 0.016 apfu. There are no apatite U-Pb data for

491   this sample but there are coexisting apatite (U-Th)/He data with a weighted mean age of 347 ±

492   65 Ma (1σ; n=5) and an additional nearby (U-Th)/He sample 09SZ-24-01 with a weighted mean

493   age of 211 ± 80 Ma (1σ; n=7). Sample 09SZ-23-01 is not entirely comparable to our ICP-MS

494   AFT data because only ^{238}U was measured and is not necessarily representative of the eU, as Th

495   and Sm contributions could make the eU much greater and add greater variability between

496   grains. To add more approximate values for eU we took the average Th and Sm concentrations

497   of the two apatite (U-Th)/He samples and used those to calculate eU for the AFT data. This

498   yields a mean eU of 14 ppm (range 11-20 ppm). Further information regarding AFT analytical

499   methods, Cl compositional data, and accompanying AHe data (sample 09SZ-24-01 at about the

500   same location) are given in Lavoie et al. (2013) and Pinet et al. (2016).

501   ***4.4 Churchill-Rae Province, Southampton Island***

502   *Sample 07CYA-M38B* is from gabbroic anorthosite bedrock on Southampton Island with a U-Pb

503   zircon inherited primary crystallization age of 3005 ± 22 Ma and a recrystallization age of 1870

504   ± 10 Ma (MSWD=1.2) due to Trans-Hudson overprinting (Rayner et al., 2011). The apatite U-Pb

505   mixture model single age peak is 1834 ± 60 Ma (2σ; n=35). The AFT sample has a pooled age of

506   341.6 ± 10.5 Ma (1σ; n=40) and a central age of 384 ± 21 (1σ) with 30% age dispersion. The

507   MTL is 12.22 ± 2.0 μm (1σ; n=132). The mean kinetic parameters for 07CYA-M38B are:

508   measured D_{par} of 1.90 μm, eU of 22 ppm (range 1-71 ppm), calculated r_{mr0} of 0.84, and measured

509   Cl of 0.024 apfu.

510   *Sample 07CYA-M133A* is a plutonic diorite from Southampton Island with a U-Pb igneous

511   crystallization age of 1842 ± 5 Ma (Rayner et al., 2011). The apatite U-Pb mixture model single

512   age peak is 1812 ± 79 Ma (2σ; n=13). The AFT sample has a pooled age of 364.2 ± 10.6 Ma (1σ;

513   n=15) and a central age of 375 ± 17 (1σ) with 16% age dispersion. The MTL is 11.57 ± 2.16 μm

514   (1σ; n=101). The mean kinetic parameters for 07CYA-M133A are: measured D_{par} of 2.26 μm,

515   eU of 74 ppm (range 7-258 ppm), calculated r_{mr0} of 0.80, and measured Cl of 0.086 apfu.

516   ***4.5 Rae craton, southern Baffin Island***

517   *Sample 09SRB-M100* is a metasedimentary semipelite within the Paleoproterozoic Hoare Bay
518   Group at Kumlien Fiord on the Cumberland Peninsula, Baffin Island. The apatite U-Pb mixture
519   model single age peak is 1674 ± 35 Ma (2σ; n=28). The AFT sample has a pooled age of 97.2 ±
520   4.3 Ma (1σ; n=35) and a central age of 102 ± 8 (1σ) with 37% age dispersion. The MTL is 12.94
521   ± 2.23 μm (1σ; n=41). The mean kinetic parameters for 09SRB-M100 are: measured D_{par} of 2.14
522   μm, eU of 22 ppm (range 1-69 ppm), calculated r_{mr0} of 0.83, and measured Cl of 0.023 apfu.

523   *Sample 14SUB-H43A* is a metamorphic garnet-biotite psammite from a Paleoproterozoic
524   metasediment/layered mafic intrusion sequence on northern Hall Peninsula, Baffin Island. The
525   apatite U-Pb mixture model single age peak is 1782 ± 38 Ma (2σ; n=25). The AFT sample has a
526   pooled age of 440.2 ± 11.4 Ma (1σ; n=25) and a central age of 442 ± 12 (1σ) with 10% age
527   dispersion. The MTL is 12.46 ± 1.72 μm (1σ; n=130). The mean kinetic parameters for 14SUB-
528   H43A are: measured D_{par} of 2.29 μm, eU of 26 ppm (range 16-35 ppm), calculated r_{mr0} of 0.82,
529   and measured Cl of 0.022 apfu.

530   ### 4.6 Grenville Orogen, southeast Quebec

531   *Sample 02NKL-871* is from a granitic orthogneiss in southeast Quebec. It is shown here for
532   comparative purposes, as it is much younger (Grenvillian) than the majority of our other samples
533   taken from Archean bedrock. The apatite U-Pb mixture model single age peak is 951 ± 38 Ma
534   (2σ; n=25). The AFT sample has a pooled age of 160.8 ± 4.5 Ma (1σ; n=35) and a central age of
535   177 ± 13 (1σ) with 38% age dispersion. The MTL is 12.27 ± 1.80 μm (1σ; n=135). The mean
536   kinetic parameters for 02NKL-871 are: measured D_{par} of 1.83 μm, eU of 31 ppm (range 2-160
537   ppm), calculated r_{mr0} of 0.85, and measured Cl of 0.008 apfu. This sample will also be discussed
538   with AFT and AHe data from the Anticosti Island (Quebec) Grenville basement sample of
539   Powell et al., (2018a), see table 1.

540

541   **5. Discussion**

542   ***5.1 AFT age relationships between eU and kinetic parameters r_{mr0} and effective Cl***

543   Using plots of central age versus U, Hendriks and Redfield (2005) proposed that REA could
544   explain the observed decrease in AFT age with increasing U content for samples from the

Fennoscandian Shield. Kohn et al. (2009) compared central ages with eU values for a larger set of Precambrian shield rocks and reported weaker or inconsistent trends, suggesting that variable Cl content rather than REA was controlling AFT annealing and age dispersion. These contrasting results are not surprising given the methods that were used. Kinetic variability or potential REA effects should be evaluated for individual grains, particularly for the samples of this study that exhibit "open jaw" radial plots (O'Sullivan and Parrish, 1995; fig. 3) that are a common feature of multi-kinetic AFT samples (e.g. Issler et al., 2005; Powell et al., 2018b; Schneider and Issler, 2019). Furthermore, it can be difficult to infer compositional controls on AFT annealing using Cl content alone, when OH and various cations can also have a significant effect on AFT annealing (Barbarand et al., 2003; Carlson et al., 1999). Combining samples of different apatite composition and/or with different thermal histories may obscure any potential relationship between AFT age and eU.

Unlike the previous studies that used the external detector method where typically up to 20 age grains are measured, we use larger sets of AFT single grain ages (up to 40 grains per sample; table 1) obtained using the LA-ICP-MS method to investigate intra-sample age dispersion with respect to eU and annealing kinetic parameters derived from detailed elemental data. Samples with the largest number of measured grains (30-40) have the largest age dispersion (21-57%) whereas those with <30 grains have much lower dispersion (10-21%; fig. 3). Clearly it is necessary to measure a sufficient number of grains in order to sample as broad a range of eU values and AFT ages as possible. Although we also observe a weak negative correlation between central age and eU (fig. 2), single grain ages spanning hundreds of millions of years, or over a billion years in some cases, show a well-defined relationship between increasing eU and younger AFT age (fig. 5). Our bedrock AFT samples generally have near end-member fluorapatite compositions based on measured Cl concentration. Some samples show a broader range in track retentivity when other kinetic parameters such as r_{mr0} (or equivalent eCl) and D_{par}, are examined but there is no clear correlation between age and apatite composition (fig. 5). Instead, the extreme variations in eU seem to offer the best explanation for the observed AFT age heterogeneity (clear correlation with age, fig. 5). The effect of eU on fission-track retentivity may have a discernible link to long residence at low temperatures in or below the partial annealing zone.

575

The interplay between eU and the other dominant kinetic parameter (i.e. Cl) becomes complex in some instances where Cl concentrations are comparatively variable or elevated, or there is relative enrichment of cations such as Fe or REE (fig. 5 and fig. 6). This is clearly demonstrated by a counterintuitive association between eU and eCl (or inverse correlation with r_{mr0}, fig. 6). The Baffin Island semipelite sample 09SRB-M100C1 demonstrates a spurious correlation between eU and eCl/r_{mr0}, which implies there is a confounding variable (e.g. thermal history) or other kinetic parameter controlling retentivity. Higher eCl (and low r_{mr0}) values signify higher retentivity, and high eU should hypothetically lower retentivity if greater damage is a proxy for enhanced annealing. Chemically-retentive grains with elevated eU that have experienced a thermal pulse may differentially anneal α-damaged FT regions with respect to grains that are lower eCl, and suggest cumulative thermal annealing in this sample was sufficient to obscure expected associations between retentivity proxies. A first-order filter for samples is examining the AFT age-eU relationship. If a sample shows that eCl is heterogeneous in 'age-eU space' with a clear negative (curvi-) linear age-eU correlation, then it can be assumed that eU is primarily driving retentivity, see Southampton Island and Superior Province samples. If clear eCl 'domains' or divisions are apparent when viewing age-eU relationships (sample 09SRB-M100C1), this suggests Cl or another cation-site element is playing a greater role in controlling retentivity. Samples with more homogenous chemical compositions and low Cl show no such relationship between eU and eCl/r_{mr0} and denote eU as a primary driver of intra-sample age dispersion, which is reflected in plots of eU versus age that show age scatter across the entire range of Cl. There is likely some threshold where Cl begins to counteract the effects of REA or dominates fission-track retention, however this seems variable between samples and conceivably has an association with thermal history.

5.2 Elemental substitutions and compositional variation

The formula for apatite when considering substitutions (Barbarand et al., 2003) can be written as $X_{10}YO_4Z_2$ where, X = mainly Ca, Y = P, and Z = F, Cl, or OH. The most common substitutions on the X site are Fe^{2+}, Mn^{2+}, Na^+, REE^{3+} Sr^{2+} and U^{4+}, whereas Si and S occur on the Y site. The trivalent (REE^{3+}) cations substitute in pairs to maintain charge balance: $REE^{3+} + Si^{4+}$ proceeds to $Ca^{2+} + P^{5+}$ and $REE^{3+} + Na^+$ to $2Ca^{2+}$ (Barbarand et al., 2003 and refs. therein). Cation

substitutions directly govern the structural integrity of the apatite lattice and there is an inverse correlation between the number of substitutions on the cation (X) and anion (Z) sites (Carpéna, 1998). It has also been shown that preferential U and Th substitution in fluorapatite or chlorapatite causes a change in volume (decrease and increase, respectively) of the apatite Ca (I) and Ca (II) polyhedron (e.g. Carpéna et al., 1988; Carpéna, 1998; Luo et al., 2009). This change results in an increase in size and distortion of the Ca (II) site, allowing for preferential substitution of U and Th at both Ca sites in chlorapatite and is an interesting observation because the Carlson et al., (1999) dataset documents that Ca substitutions tend to reduce annealing rates in apatite but may also depend on a complex relationship with mixing at the halogen site (i.e. F/Cl/OH). The results of Luo et al., (2009) demonstrate that U and Th are structurally preferred in chlorapatite, so it is expected that previous work attributed differences in AFT ages to Cl rather than eU, as Cl is a dominant control on track retentivity.

We show two examples where we try to further investigate the compositional controls on AFT grain ages from samples with high and low age dispersion. Sample PBA-98-743 from the Superior Province and 12NK-L18A3 from the northeast Slave craton are characterized by 36% and 14% dispersion, respectively (fig. 3). PBA-98-743 exhibits strong eU control on age (figs. 4 and 6), however 12NK-L18A3 does not (fig. 4). Moreover, the Slave sample is characterized by old ages despite high eU (high α-damage; see fig. 9), suggesting another kinetic control on retentivity.

Linear correlation matrices were performed on the elemental data (apfu, including OH estimates) for our samples to assess the dominant interactions between the known controls on retentivity (fig. 7; all samples shown in SI). The data were standardized first to reduce any extreme variance between elements. Correlation coefficients associated with positive correlations are shown in black and variables that are anti-correlated are in white with the size of the circle corresponding to larger or smaller correlation coefficients (fig. 7A). For the Superior Province sample all linear correlations are shown in fig. 7A, however to assess the robustness of the relationship, only those that correspond to p-values of ≤0.05 or pass at 95% confidence level were retained (fig. 7B). F and Cl are anti-correlated as expected and in this case eU is most highly correlated with Ce (r = 0.68), La (r = 0.56), Cl (r = 0.50), Y (r = 0.46), Mn (r = 0.45) and is anti-correlated with F (r = -

635 0.41). La and Ce are the most-highly correlated elements (r = 0.90). However, caution is advised

636 in interpreting these relationships because in some cases many of the grains contain low or

637 negligible elements but only a few grains are enriched and produce a statistically robust

638 correlation (fig. 7C), as is the case with eU and La/Ce. However, an overall assessment of

639 elemental abundances and apatite lattice site "preference" are contained in these data.

640 Figure 7D is a case where no clear age-eU relationship is observed and this is revealed in the

641 correlation matrix (p-values of ≤0.05) as eU is not robustly correlated with any other element.

642 The Slave craton sample is incorporating REE, Mn, Fe, Na, and Cl. The most highly correlated

643 elements are La-Ce (r = 0.97), Na-Cl (r = 0.79), Na-Mg (r = 0.76), Mn-Fe (r = 0.76), Mn-Y (r =

644 0.74), Fe-Y (r = 0.66), and Fe-La (r = 0.63). A relationship that is clear from our samples is that

645 the preferential incorporation of cation elements such as REE and U-Th (table 2) seems to

646 dominate in cases where AFT ages exhibit a negative age-eU relationship, suggesting a dominant

647 retentive control on age due to elevated eU, which agree with the results of Carpéna (1998). Our

648 elemental data suggest that in addition to common apatite varieties, we may have more "exotic"

649 apatites that heavily incorporate REE, Na, U, and Si. We have not probed for Si but that may be

650 important to monitor in future AFT studies. These associations yield some insight into retentivity

651 (AFT age) and they indicate the elements that are being incorporated into apatite grains from a

652 particular bedrock sample, which may ultimately and indirectly aid in assessment of age

653 dispersion. Our correlation matrices (see SI) also demonstrate that fluorapatite is characterized

654 by lower Cl and U-Th affinity, whereas chlorapatite shows a positive correlation between Cl and

655 eU. These relationships also suggest that if actinides are incorporated into chlorapatite, then there

656 may be a delicate balance between elevated eU (retentivity decrease) and elements that are

657 known to increase track retentivity, which may be ultimately governed by damage accumulation

658 time and specific elemental abundance. It is extremely important to point out that while many of

659 these elements are highly correlated with one another, eU is the only element that exhibits a very

660 consistent and strong (curvi)-linear relationship with AFT single-grain ages in virtually all of our

661 samples. This observation advocates for α-radiation as a governing factor for AFT annealing in

662 slowly-cooled settings.

663

664 ***5.3 Enhanced dissolution and fission track etching rates***

665 Previous work has demonstrated α-radiation-enhanced dissolution is a concern for U-rich or
666 actinide-bearing accessory mineral phases (e.g. Dran et al., 1984; Petit et al., 1985). Petit et al.
667 showed that implantation of low energy (~1 keV/amu) Pb ions, which simulate α-recoil, greatly
668 increases dissolution rate above a certain critical damage threshold of ~2.5×10^{18} α/g, dependent
669 upon mineral U (Th and Sm) concentrations and accrued time of damage accumulation. Weber
670 and Matzke (1986) examined actinide-host phases, one of which was the apatite structure
671 $Ca_2Nd_8(SiO_4)_6O_2$ that was doped with ^{244}Cm to investigate the effects on microstructure from
672 self-irradiation by α-decay and fission. They found that α-damage and fission tracks overlap at
673 high doses and leads to amorphization at ~1.1×10^{19} α/g, ~8% swelling of the crystalline volume,
674 and a factor of 10 increase in leachability. Ewing et al. (1981) document similar enhanced
675 dissolution (by a factor of ~100) in increasingly older zircons with greater accumulated damage.
676 Intuitively or hypothetically, if higher U caused enhanced track annealing, the FT analyst could
677 measure the track lengths on grain mounts where U has also been directly obtained and observe a
678 positive correlation between shorter lengths and higher U. We have examined some unpublished
679 samples where we have U from both age and length grains and there is no clear relationship
680 between length and U, accounting for both measured and c-axis projected lengths. This may be
681 due to any number of factors affecting track length collection, such as differences in etching
682 conditions (e.g. etch time, temperature, or acid strength), etching and/or annealing anisotropy,
683 variability in measured length with respect to the c-axis, U heterogeneity, or simply and most
684 importantly, the sub-random sampling of tracks for measurement. However, high U apatite
685 (highly damaged) may reveal apparently longer tracks because short tracks are difficult to
686 observe on a high track density surface – invalidating the assumption of high eU being correlated
687 with shorter tracks and suggesting that the observation of longer tracks may be more likely for
688 high eU grains. Ultimately, for AFT dating there may be no discernible differences in etching for
689 typical apatites because the induced α-damage levels in laboratory experiments are rarely
690 achieved in the geological environment.

691

692 *5.4 Considering α-recoil and fission track damage accumulation and annealing*

693 The α-damage present in apatite will increase with time as a function of the parent nuclide
694 content, but will also decrease with heating (Shuster and Farley, 2009). The negative age-eU

695   trends in our dataset (not commonly observed for apatite data) imply long residence at low

696   temperatures below those required for track annealing (or significant He retention). Our data

697   empirically support the persistence of α-recoil damage over extremely long timescales in the

698   AFT system (figs. 8 and 9) and that α-damage is characterized by slower annealing rates than

699   fission-track damage, as previously suggested (e.g. Fox and Shuster, 2014; Ritter and Märk,

700   1986; Willett et al., 2017).

701

702   We further interrogate our AFT samples by estimating the amount of α-damage they have

703   accumulated. Alpha dose is calculated following equation 5 of Nasdala et al. (2005) and is

704   expressed as α/g.

705 $$D_\alpha = 8 \cdot \frac{C_U \cdot N_A \cdot 0.9928}{M_{238} \cdot 10^6} \cdot \left(e^{\lambda 238 t} - 1\right) + 7 \cdot \frac{C_U \cdot N_A \cdot 0.0072}{M_{235} \cdot 10^6} \cdot \left(e^{\lambda 235 t} - 1\right) + 6 \cdot \frac{C_{Th} \cdot N_A}{M_{232} \cdot 10^6} \cdot \left(e^{\lambda 232 t} - 1\right) \qquad (1)$$

706   Where, C_U and C_{Th} are the actinide concentrations in ppm, N_A is Avogadro's number, and M_{238}

707   (etc.) are the molecular weights of the parent isotopes, and λ_{238}, λ_{235}, λ_{232} are the decay constants

708   for each. The t in the equation refers to the integration or accumulation time for α-particle self-

709   irradiation. Traditionally, for zircon this time is taken as the time since crystallization and is

710   presumably a reasonable assumption, however this becomes more difficult to assess for other

711   minerals such as apatite that are more prone to greater damage annealing at moderate

712   temperatures of <200°C.

713   The most difficult assumption regarding α-dose estimation is the integration time for self-

714   irradiation, and here we refer to the integration time as the "effective dose accumulation time"

715   (t_{EDA}). Typically it is believed that α-damage is fully annealed at temperatures of ~150°C (Weber

716   et al., 1997) and if fission tracks are fully annealed at ~125°C (Green et al., 1986) then the oldest

717   AFT age would yield a conservative estimate for t_{EDA}. A limitation in adhering to strict

718   temperature limits is that apatite composition can introduce differences in the thermal sensitivity

719   of an individual grain, and that the time spent at a given temperature is just as important, if not

720   more so for cratonic rocks. The trade-off between time and temperature, with respect to

721   annealing, is analogous to laboratory annealing experiments where the same degree of annealing

722   can be achieved at higher temperatures in a shorter time, or at lower temperatures over a longer

723   duration. Therefore, we optimistically estimate the t_{EDA} for apatite as the mean of the 2σ

724   minimum apatite U-Pb isotopic sum age for the sample. The apatite U-Pb age estimate for AFT

725   t_{EDA} seems to be a suitable approximation, however this should not be viewed as a rigorous

726   temperature-based appraisal because the large U-Pb apatite errors are in essence providing a

727   crude intermediary between the oldest representative AFT age (~track retention age) and isotopic

728   closure for the U-Pb system. We are currently more interested in observing data trends rather

729   than establishing absolute relationships, and as more data are collected on the [238]U percolation

730   dose threshold and the temperatures at which α-damage accumulation in different apatite

731   compositions is appreciable, there can be improvements to this approach as the t_{EDA} uncertainties

732   are high.

733

734   An example of the relationship between α-damage and cooling age is shown in figure 8 where

735   AFT and AHe data from the same location (Pinet et al., 2016) are plotted against eU and

736   transposed into α-dose. The apatite grains show a modest range in eU but interestingly the AFT

737   data only capture the low eU and the AHe data have a greater spread in eU (fig. 8A,B). This

738   observation certainly suggests preferential selection of grains for each method, perhaps outside

739   of the established routine of choosing pristine whole grains for (U-Th)/He analysis. The black

740   dashed line is the [238]U α-recoil track percolation threshold of 1.9x10[16] α/g from Ketcham et al.,

741   (2017) and is the point where diffusivity is expected to increase due to damage connectivity

742   creating fast-path diffusion for the (U-Th)/He system. These data clearly demonstrate the

743   increase in AHe age going from low eU/low α-dose and increasing in age until the percolation

744   threshold is reached whereby a decrease in age follows (this is very similar to the observed

745   behaviour for zircon U-Th/He data for fission-track percolation Guenthner et al., 2013). The

746   AFT data are mostly above the U percolation threshold even though those grains have low eU,

747   whereas the AHe grains have higher eU concentrations/damage and are even younger. The

748   chronometer ages plot above the damage threshold due to long t_{EDA}, which dominates any effects

749   of high or variable eU between single grains. When examining samples, the difference in t_{EDA}

750   can explain why very different U and Th amounts between samples can result in similar overall

751   age-eU trends. Visually the data display remarkable adherence to the α-recoil track percolation

752   threshold, despite the fact that the data are from different thermochronometers, suggesting α-

753   damage affects apatite diffusive processes and has repercussions for both damage annealing and

diffusivity. Sample 13JP10 from the Grenville basement of Anticosti Island (Powell et al., 2018a) potentially spent ~275 Ma at temperatures >120-150°C, or experienced an episodic pulsed history to these high temperatures, which suggests that thermal resetting completely decoupled α-damage and fission track damage accumulation from one another (fig. 8C,D). It is also worth mentioning that 13JP10 underwent significant thermal annealing and is also one of the only samples shown in figure 2 with 40 dated age grains and low age dispersion (16%).

Our α-dose plots imply that at least some fission tracks are impacted by α-recoil tracks. At this time it is not entirely clear why AFT ages behave similarly to AHe ages with respect to the recoil damage percolation threshold, however it may be due to their shared dependence on diffusive mechanisms that affect track annealing and ^{4}He retentivity. We envision difficulty in trying to develop a model to jointly explain these damage types, as the dimensions, frequencies, and timescales (t_{EDA}) are very different. Now we examine our Canadian Shield AFT data with respect to the ^{238}U α-recoil percolation threshold and discuss these relationships.

Figure 9A shows AFT data from the Canadian Shield selected from table 1. All AFT samples with long (and similar) t_{EDA} >1 Ga plot to the right of the damage threshold, whereas Grenvillian basement samples 02NKL-871 and 13JP10 from Powell et al. (2018a) with shorter t_{EDA} <1 Ga show an increase and subsequent decrease in AFT ages before and after the damage threshold, respectively. To better understand the damage relation with AFT age, it is notable that a very high eU sample 12NK-L18A3 displays high damage and high eU variance (σ^2) between single grains (mean eU: 339 ± 158 ppm, 1σ) resulting in a relatively low spread in single-grain ages (403 ± 71 Ma (2σ, n=26)) but moderate spread in damage level. There is no clear age-eU relationship for this sample (fig. 5). Conversely, sample 13LVA04 has very low eU (and low σ^2; mean eU: 6 ± 1 ppm) and plots on the percolation threshold resulting in extreme age variability (560 ± 329 Ma (2σ, n=40)). High age scatter is expected for samples exhibiting high eU variability and especially for those near the percolation threshold – as this would be the region of greatest sensitivity to subtle changes in crystal damage and therefore changes in track annealing and effects on AFT age.

783

We also chose younger samples from the recent literature that have been dated by AFT and U-Pb (when possible) to compare to our Canada dataset. AFT samples from younger bedrock terranes in active tectonic settings including those from Sakhalin Island (Okhostsk), Russia (Glorie et al., 2017), the Yukon-Tanana area of central Alaska (Dusel-Bacon et al., 2016), the Wrangellia Terrane near Mt. Logan, Alaska (Enkelmann et al., 2017), and the northern Chilean Andes (Rodríguez et al., 2018). We also compared these to single-grain analyses of the Durango (eU = 81 ± 7 ppm, 1σ, n=300) and Fish Canyon Tuff (eU = 42 ± 15 ppm, n=300) AFT standards dated by P. O'Sullivan. This comparison was done to assess if there is similar behaviour with respect to damage accumulation and adherence to the α-recoil percolation threshold that is demonstrated by our older cratonic samples. The major limitation for finding suitable published data is that the majority of studies do not publish single-grain AFT analyses (only AFT sample summaries) and that apatites from younger rocks are not typically dated via LA-ICP-MS U-Pb because it is impractical due to the low amounts of U, Th, and Pb and the high initial common Pb incorporated in apatite (Chew et al., 2011). Published samples where Th was not reported or the EDM was used, we simply used the U amount to estimate the α-dose (Wrangellia and Russia), and examples where U-Pb data was unavailable we used the oldest individual AFT grain age or another high-T thermochronometer, i.e. $^{40}Ar/^{39}Ar$ biotite for Wrangellia to estimate t_{EDA}.

We give a brief description of each sample here, although for more complete information the reader should consult the cited reference. The Russian Sakhalin Island sample SK14-03 comes from a granodiorite with a zircon U-Pb age of 43.3 ± 0.6 Ma and an apatite U-Pb age of 38.9 ± 5.5 Ma. Twenty-six single-grain LA-ICP-MS AFT analyses yield a pooled age of 19.3 ± 2.1 Ma and central age of 18.4 ± 1.6 Ma (avg. ^{238}U=32 ppm; Glorie et al., 2017). The Yukon Alaska sample 09AD-240 is from a leucogranite with a SHRIMP zircon U-Pb igneous crystallization age of 191 ± 5 Ma and a pooled fission track age of 48.9 ± 3.9 Ma (avg. eU=12 ppm, n=40). The t_{EDA} for this sample was estimated by evidence that Mesozoic granitoids intruded the country rock and cooled to <300°C by ~185 Ma (Dusel-Bacon et al., 2016). Sample LL07 was collected from the Chilean Andes Main Cordillera north of 31.5°S from the Upper Cretaceous-Paleocene intrusive belt (Rodríguez et al., 2018). This sample has an AFT age of 31 ± 1.8 Ma (avg. eU=73

812   ppm, n=40) with a biotite K/Ar age of c. 67 Ma, taken as an approximation for t_{EDA} (all ages are
813   quoted at the 1σ level).

814   Figure 9B shows that all of the younger samples from the literature plot to the left of the α-recoil
815   percolation threshold and do not display the same age-dose patterns as the old cratonic samples.
816   This further demonstrates that apatites characterized by high or variable eU still require
817   significant time to accumulate radiation damage to produce an effect on AFT ages.

5.5 Multi-kinetic interpretation and thermal history modeling

819   The goal of most AFT studies is to model the age and track length data to make inferences about
820   past thermal history and geologic processes. This can only be achieved if we have a robust
821   understanding of the kinetics that govern the thermochronometers that we use. There are multiple
822   fission track annealing proxies such as measured Cl, r_{mr0}, and D_{par} that assist us in deconvolving
823   the annealing complexity contained within samples, however these tools are not perfect and in
824   some cases offer little help in understanding multi-kinetic samples. Our Canadian Shield samples
825   are typically compositionally homogeneous, which makes multi-kinetic interpretation
826   exceedingly problematic. Figure 10 shows two examples of an exploratory attempt at utilizing
827   the AFT age-α-dose (eU) relationship that is common to all of our cratonic samples. Samples
828   02NKL-871 and 11CXAN017 are very different in terms of calculated t_{EDA} and are used as
829   examples for multi-kinetic interpretation. We display the grain ages for each sample on a radial
830   plot (fig. 10 A, E) and perform age mixture modeling as before to identify statistically significant
831   age populations. These age populations are then plotted in terms of their eCl (fig. 10B, F) and
832   there is complete overlap between all populations, which invalidates clear compositional
833   separation due to chemical homogeneity between grains spanning the typical eCl error range. If
834   traditional compositional proxies suggest our sample is probably common F-apatite (fig. 10B, F),
835   but there is high age dispersion, we can be certain that another factor such as eU may be
836   controlling retentivity (fig. 10C, G). When these samples are examined in terms of α-dose it
837   becomes obvious that there are grains of similar age – for different reasons. The low eU grains
838   for sample 02NKL-871 have accumulated less damage or are generally low retentivity that have
839   probably experienced some thermal annealing, whereas the high eU/highly damaged grains have
840   experienced REA. There is undoubtedly a competition between fission track and α-damage
841   ingrowth and annealing that occurs and is further complicated by minor thermal annealing

842 events, as fission tracks and α-damage vary in both temperature sensitivity and natural
843 abundance. The same level of thermal annealing would preferentially remove more fission
844 damage, but the remaining α-damage would still play a role in overall retentive behaviour. The
845 separation of kinetic populations is more apparent for grains that have migrated across the α-
846 recoil percolation threshold due to longer t_{EDA} (fig. 10H). The age peaks picked by the radial plot
847 mixture modeling are based on age (and U-related age precision) and match the age populations
848 identified by the differences in α-dose between the two groups for sample 11CXAN017. In these
849 cases we have identified a potential path forward in terms of separating kinetic populations by
850 eU or α-dose for apatites in slowly-cooled rocks.

851 *5.6 Implications for the apatite fission track and (U-Th)/He thermochronometers*

852 Carpéna et al. (1988) discuss one of the earliest known examples of the effects of U-Th on AFT
853 ages from the In Ouzzal carbonatites in Africa where they suggested that higher radiation
854 damage causes apatite lattice expansion and increases the thermal sensitivity of fission tracks to
855 thermal annealing events. Carpéna and Lacout (2010) carried out thermal annealing experiments
856 on synthetic apatites doped with ^{235}U and irradiated with thermal neutrons to induce fission.
857 They compared the synthetic apatite (no α-damage) to natural apatite to demonstrate that fission
858 tracks in the synthetic apatite needed higher temperatures and longer time to reach the same
859 degree of annealing when compared to natural apatite. Experimental evidence has also shown
860 that α-particle irradiation-induced annealing occurs in buried amorphous layers in natural
861 Durango fluorapatite (Ouchani et al., 1997) and similar behaviour has been observed in silicate
862 apatite structures, which are more thermally stable than natural apatite (Weber et al., 1986;
863 Weber et al., 1997). The latter studies were performed on thick amorphous layers, which should
864 be more difficult to anneal than amorphous tracks, supporting the idea that fission track
865 annealing could be enhanced by α-radiation. Non-thermal annealing of α-recoil damage and
866 recovery of crystalline structure from (pre-damaged) fully-amorphous Durango apatite
867 specimens was observed by *in situ* transmission electron microscopy (Li et al., 2017). Damage
868 recovery through α-healing has also been recently demonstrated for monazite, suggesting that
869 natural monazite, like apatite, never becomes amorphous due to the effects of α-recoil (Seydoux-
870 Guillaume et al., 2018). These experiments and observations support REA and imply that cratons
871 would be the ideal natural laboratory because rocks reside at low temperatures (<100°C) over

872 hundreds of millions to billions of years favouring high α-damage accumulation in natural apatite

873 compositions. In the case of lower eU concentrations, a long t_{EDA} could also create the same

874 conditions for lowering annealing activation energy.

875

876 We are unsure if α-particles directly anneal fission tracks, as posited by Hendriks and Redfield

877 (2005), or that perhaps α-recoil acts to destabilize fission tracks and therefore affects annealing

878 rates. More work is required to properly evaluate the thermal and temporal sensitivity of

879 different apatite compositions and the kinetics of α-recoil and fission-track damage. The process

880 or mechanism by which α-recoil damage destabilizes fission tracks is not fully understood.

881 However, some hypotheses are that (1) lattice distortion from accrued α-damage may increase

882 the thermal annealing susceptibility of apatite, (2) α-decay ionization and electrical excitation

883 cause fission track defect annealing via self-heating over 100s-1000 My timescales, or (3) α-

884 damage interferes with or "connects" with fission-tracks directly, disrupting the crystal lattice,

885 which in turn yields a fission track configuration that is easier to anneal. Elemental substitutions

886 may act in a similar manner as hypothesis (3) by elements of different size or lattice site

887 affecting annealing behaviour.

888

889 We know that α-damage zones (Farley, 2000; Shuster et al., 2006), vacancies (Gerin et al.,

890 2017), porous voids (Zeitler et al. 2017), and dislocations (McDannell et al., 2018b) increase [4]He

891 retentivity and act as diffusive traps for (U-Th)/He dating. In the case of AFT analysis, REA may

892 be a purely structural effect from lattice distortions or convolved with the fact that in some cases

893 those substitutions happen to be high α-emitters, thus introducing the likelihood for the

894 degradation of fission-track integrity that is most evident when thermal annealing is a secondary

895 concern. We can envision the structural relaxation phase of α-damage annealing being very

896 important in apatite that has accumulated greater damage, which may lead to differences in

897 annealing due to enhanced lattice recovery during any thermal perturbation with respect to an

898 undamaged apatite. It is not clear how other Ca-site substituting elements such as Fe that

899 increase fission track retentivity, would play a role in counteracting REA and would obviously

900 only do so if present in sufficient quantity within the lattice. A corollary exists in zircon where

901 greater U and Th content increases microstructural deformation as further development and creep

902 of lattice dislocations cause enhanced diffusivity of these elements (Timms et al., 2006). Crystal
903 lattice defects related to α-recoil might be a primary contributor to fission track instability. This
904 could either be directly, or by association with substituting α-emitting parent nuclides such as U
905 and Th. Interference between lattice defects due to α-recoil and fission-track defects could
906 invariably result in α-recoil causing sufficient damage to facilitate annealing, especially given the
907 rarity of fission tracks with respect to α-recoil tracks. These effects could presumably overwhelm
908 apatite fission tracks from rocks with variable U and Th concentrations that have been residing at
909 near-surface conditions for hundreds of millions of years. In other cases involving more complex
910 shallow burial and exhumation events, some amount of α-damage may be preserved for up to a
911 billion years or more and never fully annealed. In these scenarios, thermal annealing is mostly
912 insignificant at <60°C, but α-induced damage could cumulatively modify the apatite lattice in
913 proportion to the U and Th, making fission tracks unstable and driving differential annealing at
914 low temperatures – thereby yielding large AFT single-grain age dispersion. This is likely
915 amplified by longer damage accumulation times and is more noticeable in samples with a range
916 of eU. Fission tracks and α-damage both undergo annealing via diffusive processes (Ritter and
917 Märk, 1986), which are regulated by crystallographic damage level; therefore they should be
918 viewed and treated as a damage continuum with different timescale and kinetic dependencies.

919 ### 6. Recommendations and questions for future work

920 The effects of REA on AFT ages in slowly-cooled settings is a complex problem that requires
921 sufficient data to be able to evaluate relationships between chemical composition and age. Some
922 factors to consider in future work to assist in addressing REA include:

923 1. Acquire enough age grains to capture and to characterise intra-sample AFT age
924   dispersion. We recommend counting a minimum of 35-40 grains (dependent on sample
925   quality), especially given the ~10-20% dispersion for <25 measured grains versus ~30-
926   40% dispersion for >30 grains quoted in figure 3.
927 2. Collect detailed elemental data for every sample including length and age grains; e.g.
928   measured Cl is insufficient and could give misleading results. The acquisition of F, Na,
929   Mg, P, S, Cl, Ca, Mn, Fe, Sr, Y, La, Ce, and Si at the very least should be carried out,
930   since many of these elements are known to affect apatite damage retentivity. The

measurement of U, Th, and Sm on length grains (we did not do this for our samples) may also be beneficial for interrogating potential AFT length-eU relationships.

3. Acquire apatite U-Pb age data to estimate t_{EDA}. In cases where U-Pb data are lacking and a broad range of U has been sampled within an AFT dataset, the oldest reliably measured AFT age seems to be a satisfactory minimum time estimate of dose accumulation.

4. If cratonic bedrock samples are to be treated as multi-kinetic for thermal history modeling, evaluating grains in terms of eU may be a suitable kinetic proxy alternative for separating kinetic populations. The influence of apatite composition on annealing needs refinement and currently the choice of r_{mr0} equation is important and further work is needed to constrain the relationship at high and low retentivity where existing models do not sufficiently capture variability in retentivity.

7. Conclusions

Apatites from bedrock samples across many areas of the Canadian Shield show coincident high single-grain age dispersion and variable eU. There are no other clear intra-sample, compositional controls such as Cl, Fe, or REE substitution that demonstrate a strong relation with AFT age. In some isolated cases there are some grains enriched in elements known to enhance fission-track retentivity, however these are typically only a few grains from within a sample. The complexity of our AFT dataset further establishes the necessity of acquiring compositional data for interpreting apatite fission-track analyses and our data strongly support the notion that REA from α-damage is related to the eU content within apatite. We stress that this does not invalidate AFT analysis, although care should be taken to properly evaluate slowly-cooled rocks. Complications arise between co-existing, specific elemental substitutions that independently act to either enhance or reduce fission track annealing. The exact mechanism for enhanced annealing is likely multifaceted but may be due to α-damage affecting tracks directly, α-damage and elemental substitutions causing lattice defects that promote track instability and lower thermal annealing resistance, α-damage self-healing reducing lattice damage and affecting fission tracks, or a combination of these effects that are exacerbated in settings where thermal annealing is minimal and timescales for α-damage accumulation are long.

1397 **FIGURE CAPTIONS**

1398 **Figure 1.** Map of the Canadian Shield with simplified geologic domains modified from Whitmeyer and
1399 Karlstrom (2007). Bedrock AFT samples are shown as circles with their corresponding central age, red
1400 points are LA-ICP-MS AFT samples and the orange point is the published Pinet et. al. (2016) sample.
1401 Areas in purple show Paleozoic succession of Hudson Bay, sub-basins, and surrounding Arctic platform,
1402 which imply bedrock has been at or near the present surface since (at least) the Ordovician. Refer to table
1403 1 and text in section 4 for more information on AFT samples. Missing section in central Hudson Bay is
1404 younger overlying Mesozoic-Cenozoic sediment. Quebec Grenvillian and Cumberland Peninsula, Baffin
1405 Island samples are shown and discussed for comparison only, as they have a more complex thermal
1406 history compared to the Canadian Shield samples. Sample ID shown in box near central age value for
1407 each sample, refer to table 1. THO = Trans-Hudson Orogen; GSL = Great Slave Lake shear zone; STZ =
1408 Snowbird Tectonic Zone; CP = Cumberland Peninsula; HP = Hall Peninsula; AB = Athabasca Basin; TB
1409 = Thelon Basin.
1410

1411 **Figure 2.** (A) Conventional plot of eU content versus AFT age as well as mean track length for all
1412 bedrock samples. Other than the two high eU examples there is a decrease in age with eU across all
1413 samples. A simple least-squares linear regression (removing the two eU outliers) produces an R^2 value of
1414 0.36. (B) Highest eU grains clearly have the shortest MTL, however there are not enough intermediate-to-
1415 high eU data to confidently extrapolate the relationship. (C) All single grains shown in F and Cl weight
1416 percent. Barbarand et al., (2003) demonstrate Cl does not dominate the apatite structure (retentivity) until
1417 >~0.35 wt. % or >0.1 apfu. Our dataset is dominated by F-apatite and/or hydroxyl-bearing F-apatite
1418 varieties.

1419 **Figure 3.** Radial plots (log transformed) from DensityPlotter v. 8.2 for LA-ICP-MS AFT data. "Open
1420 jaw" radial plots are typical of our dataset and are generally interpreted as meaning that there is a complex
1421 mixture of AFT ages that are non-Poissonian in character. Refer to table 1 for sample information. As an
1422 example of single-grain age dispersion effects, we have shown the two-component mixture model ages
1423 associated with age peaks of ca. 160 and ca. 75 Ma for sample 09SRB-M100. This illustrates how the
1424 central age for a sample can be misleading in cases of high dispersion. For sample 14SUB-H43A the
1425 opposite is true as this sample only has 10% age dispersion and lower *n*. Stars denote published samples
1426 from Pinet et al. (2016) and Powell et al., (2018a).

1427 **Figure 4.** Fission track length distributions for each sample shown in figure 3. Length distributions are
1428 presented as frequency (%) in 1 μm bins with equivalent normal distributions shown for the mean ± 1σ
1429 (solid, blue curve) and the mode (dashed, red curve). A mismatch between the equivalent normal
1430 distributions is taken to suggest bimodality and more complex, episodic thermal histories.

1431 **Figure 5.** Bedrock sample AFT age versus eU and eCl for each sample in Table 1. Notice that each
1432 sample has a negative age-eU trend for single grains, only sample 12NK-L18A3 does not and this is
1433 discussed in section 5. There is no clear age relationship with eCl (r_{mr0}). Note: samples are coloured the
1434 same in figure 5 and figure 9. In the few cases where a grain was not probed, we used the average sample
1435 eCl value as a placeholder.
1436

1437 **Figure 6.** Examples of the relationship between eU and AFT age, eCl, and r_{mr0}. (A) The Baffin Island
1438 sample exhibits behaviour indicative of Cl or another element controlling retentivity (> than any eU
1439 effect), whereas the other samples suggest eU is controlling retentivity (B-C). The panels in C are age-
1440 normalized to show both samples PBA-98-743 and 03-GRS-013 together. Unfilled circles are values
1441 outside the color ramp maximum. Trend lines (reduced major axis regression) are for visual purposes
1442 only, to highlight the spurious correlation (upper panel) and the lack of correlation (dashed, middle panel)

1443   between eU and eCl (or r_{mr0}). The color ramp change from red to blue is arbitrarily chosen to be the
1444   approximate mean eCl value of all the grains. Panels D-F: Scatter plots of other Canadian Shield AFT
1445   examples. (D) An example from Pinet et al. (2016) showing the relationship between ^{238}U and age. The
1446   relation is similar to our data except not as well defined given that there are a low number of grains dated
1447   and eU was not calculated, and eCl values are all similar and negative suggesting end-member apatite
1448   composition. (E) Sample 09SRB-M100C1 from Baffin Island shows a spurious relationship between AFT
1449   age and kinetic parameters eU and eCl/r_{mr0} (discussed in text, shown in fig. 6A) that is not readily
1450   apparent when eCl is plotted against AFT age shown here. This sample also underwent episodic thermal
1451   annealing. (F) Sample 14SUB-H43A also from Baffin Island displays lower eU variability than most
1452   samples and all single grains are in a range of "typical apatite" eU, it also has characteristic highly
1453   clustered positive eCl values suggesting low kinetic variability between grains. This relationship results in
1454   the appearance of less age variability, which may be naturally inherent to the sample or a result of
1455   unintended grain selection preference.

1456

1457   **Figure 7.** Correlation matrices for standardized EPMA compositional analyses. Analyses are for Cl, eU,
1458   F, Fe, Mg, Mn, Na, S, Sr, and REE (Ce, La, Y) in wt. % shown in hierarchical clustering of correlation
1459   coefficients and (B and D) only show correlations with p-values <0.05 or at the 95% confidence level.
1460   Positive (+1, black) or negative (anti-) correlation (-1, white) is shown with the size of the corresponding
1461   circle equal to the linear correlation coefficient (i.e. small circle is low correlation coefficient and *vice*
1462   *versa*). Notice the anti-correlation between F and Cl as expected. (A, B) Examples are shown for the
1463   Superior Province sample PBA-98-743 that displays eU variability in relation with single-grain AFT age
1464   (fig. 3 and fig. 5) versus sample 12NK-L18A3 with very high eU (>>100 ppm) and no obvious age-eU
1465   relationship (D). Note that care is required during interpretation of these relationships, as some grains
1466   may seem highly correlated but are represented by only a few EPMA analyses/grains, where the majority
1467   of grains are zero/below detection limit, which is typically the case for REE, seen in panel C plots of
1468   normalized eU, Ce, and La for sample PBA-98-743. Best-fit linear trend (black line) and correlation
1469   coefficient (r) are shown for each plot in C. The SI document shows correlation coefficients for each AFT
1470   sample (table S1) and correlation matrices for each sample (fig. S1).

1471   **Figure 8.** Example of both AFT and AHe data from Melville Peninsula with respect to α-dose from Pinet
1472   et al., (2016). **(A)** AFT (sample 09SZ-23-01; circles) and AHe ages (samples 09SZ23-01 and 09SZ24-01;
1473   hexagons) with respect to eU. The measured ^{238}U value is used as a proxy for eU here. This is a good
1474   approximation because most accompanying AHe single grains have low Th, <10 ppm. **(B)** AFT and AHe
1475   ages plotted against the estimated α-dose. The AFT data are older vintage without U-Pb ages; therefore
1476   we used the t_{EDA} from nearby AFT sample 10CXAD-086. **(C-D)** The same plot as A and B, but for
1477   sample 13JP10 on Anticosti Island (Powell et al., 2018a). There is no clear relationship between age and
1478   eU for this sample.

1479   **Figure 9.** Plot of estimated α-dose vs. age for selected Canadian Shield AFT samples summarized in table
1480   1 and shown on fig. 1. Samples with long t_{EDA} plot at high damage levels above the threshold and show
1481   negative age-α-dose correlations, whereas samples with shorter t_{EDA} show the expected positive
1482   relationship at low damage below the percolation threshold. Collectively these samples capture the full
1483   range in α-dose or damage level for our dataset. 13LVA04 and 12NK-L18A3 demonstrate the effect of
1484   low/high eU variance (σ^2) on α-dose. Black dashed line is the percolation threshold from Ketcham et al.,
1485   (2017). Lower panel: estimated α-dose from young samples taken from published literature. All grains
1486   fall below the ^{238}U damage percolation threshold, implying no significant damage effects on AFT age.
1487   Sample 13JP10 shown on both plots for reference. Single-grain age errors not shown on plots for clarity
1488   but AFT age percent error range (1σ) for each sample is shown beside the sample ID. Note: Wrangellia
1489   sample plots off of scale at low α-dose.

1490   **Figure 10:** An example of visualizing multi-kinetic samples in terms of composition and radiation
1491   damage for thermal history modeling. Panels are read vertically for each sample. **(A, E)** Samples 02NKL-

1492 871 from Quebec and 11CXAN017 from Melville Peninsula are characterized by high dispersion and fail
1493 the X^2 test. Radial plots show age populations based solely on mixture modeling. Note that age peak 1 for
1494 11CXAN017 contains noticeably higher precision grains (i.e. high eU). **(B, F)** AFT age plotted against
1495 eCl for each sample. Points are colors by their respective age population shown in the radial plot panels.
1496 **(C, G)** AFT ages are colored by eCl (same scale for each sample) and plotted against α-dose. There is
1497 complete compositional overlap between populations. **(D, H)** The same plots as C and G only here the
1498 age populations are instead colored by their respective age populations identified in the radial plot
1499 mixture models. Note that grains of similar age (in D) fall above and below the ^{238}U α-recoil percolation
1500 threshold (dashed black line).

1501
1502 **Table 1.** Summary of apatite fission track results from across the Canadian Shield (see fig. 1 for
1503 locations). All U measurements used for age calculations were obtained by LA-ICP-MS analysis. All of
1504 our samples fail the X^2 test. Percent difference between the central and pooled age is shown. Single-grain
1505 age span between the oldest/youngest grains (not including error) shows the AFT heterogeneity within
1506 samples and eU range is given with the mean eU in brackets. Sample 03-GRS-013 has a single
1507 anomalously old grain, which refers to the age span value in brackets. Refer to text for discussion of
1508 results. Note: some single grains within samples were unable to be probed or do not have chemical data,
1509 therefore an effective Cl/r_{mr0} value was unable to be calculated for those grains, in these instances the
1510 average respective kinetic parameter value for the entire dataset was used for plotting purposes. See SI for
1511 full AFT dataset.
1512

1513 **Table 2.** Pearson correlation coefficients for all Canadian Shield samples where eU correlated with other
1514 elemental data. All samples are shown in the SI with the ranked r-values for the top 20 elemental pairs for
1515 each sample.
