Abstract. Using 65,133 hourly averages of transpolar voltage (Φ_{PC}) from observations made over 25 years by the SuperDARN radars, with simultaneous AL and interpolated am geomagnetic indices, we study their optimum interplanetary coupling functions. We find lags of 18, 31 and 45 min. for Φ_{PC}, am and AL respectively, and fit using a general coupling function with three free fit exponents. To converge to a fit, we need to average interplanetary parameters and then apply the exponent which is a widely-used approximation: we show how and why this is valid for all interplanetary parameters, except the factor quantifying the effect of the clock angle of the interplanetary magnetic field, $sin^d(\theta/2)$, which must be computed at high time resolution and then averaged. We demonstrate the effect of the exponent d on the distribution, and hence weighting, of samples and show d is best determined from the requirement that the coupling function is a linear predictor, which yields d of 2.50±0.10, 3.00±0.22 and 5.23±0.48 for Φ_{PC}, am and AL. To check for overfitting, fits are made to half the available data and tested against the other half. Ensembles of 1000 fits are used to study the effect of the number of samples on the distribution of errors in individual fits and on systematic biases in the ensemble means. We find only a weak dependence of solar wind density for Φ_{PC} and AL but a significant one for am. The optimum coupling functions are shown to be significantly different for Φ_{PC}, am and AL.

Plain Language Abstract. Coupling functions are mathematical combinations of variables observed in the solar wind, just before it impacts near-Earth space. They are used to predict the

30 effect that the solar wind will have (or, for retrospective studies, will have had) on the space-

31 weather environment of the Earth. There is a very wide variety of proposed optimum forms for

32 coupling functions in the literature, some of which work better than others and we show which

33 performs best depends on which terrestrial disturbance indicator we are trying to predict and on

34 what timescale. We look at the validity of some commonly-used assumptions made when

35 compiling a coupling function and, using an unprecedentedly large data set of two different

36 types of terrestrial space weather disturbance indicator, we derive the optimum coupling

37 functions and their statistical uncertainties. We show that that the required coupling functions

38 are significantly different in the two cases. The results establish some important principles for

39 the development of these coupling functions and show they need to be tailored to the specific

40 space weather disturbance indicator and timescale that they aim to predict.

41 **Main points**

42 • 1. Using a very large dataset we analyze the sources and effects of noise in correlation studies

43 used to derive solar wind coupling functions

44 • 2. We study effects of weighting by the distribution of samples which varies with the choice

45 of IMF orientation factor and averaging timescale

46 • 3. The optimum coupling functions for transpolar voltage and planetary geomagnetic activity

47 are significantly different.

48 **1. Introduction.**

49 Coupling functions are combinations of interplanetary parameters that are used to

50 quantitatively predict terrestrial space weather indicators and indices. They should have a

51 linear relationship with the index or measured parameter that they aim to predict. There are a

52 great many combinations that have been proposed and tested since correlations between

53 interplanetary parameters measured by spacecraft and terrestrial disturbance indices became

54 possible (*Arnoldy*, 1971). The concept of a combination of parameters capturing their net

55 influence (i.e., a coupling function) grew out of the PhD studies of *Perreault* (1974). An

56 excellent review of the development of coupling functions, the theories behind them and the

57 empirical fits, has been given by *McPherron et al.* (2015).

58 Some coupling functions are theoretical in origin, whereas others are from empirical fits to

59 data. However, in truth all are, to some degree, a hybrid of the two. This is because

60 theoretical coupling functions almost always have to use coefficients, exponents or branching

61 ratios that are defined empirically. Conversely, empirical coupling functions employ on

62 formulations and parameters that are rooted in theory. We should also note the role of

63 numerical global simulations in developing coupling functions. These have the advantage of

64 testing the coupling function in unusual regions of parameter space; however, as always with

65 models, the validity of the results depends on the assumptions, parameterizations and

66 resolutions used in setting up the model.

67 Coupling functions have generally, but not exclusively, taken the basic mathematical form of

68 the product of measured parameters, each to the power of an exponent. Parameters used have

69 been the interplanetary magnetic field (IMF), $B = |\vec{B}|$ or its transverse component

70 perpendicular to the Sun-Earth line, $B_\perp$; the solar wind speed, V_{SW}; the solar wind number

71 density N_{SW} or its mass density $\rho_{SW} = m_{SW}N_{SW}$ (where m_{SW} is the mean ion mass); and (for

72 timescales shorter than about 1 year), a factor to allow for the orientation of the IMF in the

73 Geocentric Solar Magnetospheric (GSM) frame of reference, such as the clock angle in GSM,

74 θ. We here denote magnetic field exponents by a, mass density or number density exponents

75 by b, solar wind speed exponents by c and IMF orientation factor exponents by d.

76 Some improvements to this basic multiplicative form have been suggested in the form of

77 additive terms. For example, *Newell et al.* (2008) proposed adding to a term designed to

78 predict the dayside magnetopause reconnection voltage with a smaller term to predict the

79 voltage generated by non-reconnection "viscous-like" interaction. *Lockwood* (2019) proposed

80 a development to energy-transfer coupling functions whereby, in addition to the energy

81 extracted from the dominant energy flux in the solar wind (namely the kinetic energy flux of

82 the particles), the smaller one due to the solar wind Poynting flux is added. Given that the

83 Poynting flux in the solar wind is two orders of magnitude smaller than the particle kinetic

84 energy flux, this appears an unnecessary complication: however, the Poynting flux enters the

85 magnetosphere without the relative inefficiency with which kinetic energy of the solar wind is

86 converted into Poynting flux by currents flowing in the bow shock, magnetosheath and

87 magnetopause (*Cowley*, 1991; *Lockwood*, 2004; *Ebihara et al.*, 2019).

88 Other, more complex, forms with combinations of additive and multiplicative terms have
89 been proposed (e.g., *Borovsky*, 2013; *Luo et al*. 2013). The formulation of *Luo et al*. (2013)
90 aims take account of daily and seasonal variations in the terrestrial space weather index
91 predicted (that are due to station locations and orientation of the Earth's dipole) and non-
92 linearities caused by the expansion and contraction of the polar cap as solar wind driving
93 varies. It also removes rapid fluctuations using low-pass filters. The result is that it is highly
94 complex and, as noted by *McPherron et al.* (2015), it is unclear how many free parameters are
95 present in this coupling function, but they estimate that it is of order 35. Because these more
96 complex formulations add to the number of free fit parameters, this greatly increases the
97 problem of statistical "overfitting" (*Chicco*, 2017).   Overfitting occurs when a fit has too
98 many degrees of freedom and it can start to fit to the noise in the training data, which is not
99 the same as the noise in the test or operational data. As a result, the fit has reduced predictive
100 accuracy. This is a recognized pitfall when signal-to-noise ratio in the data is low, as is
101 usually the case in disciplines such as climate science (*Knutti et al.,* 2006) or population
102 growth (*Knape & de Valpine*, 2011), but has not often been considered in space physics in the
103 past. However, this is now changing with the advent of systems analysis of the magnetosphere
104 and the application of machine-learning techniques to space weather data (e.g., *Camporeale*,
105 2019; *Stephens et al.,* 2020). Overfitting is a problem for the generation of coupling functions
106 because there are a great many sources of noise, not all of which have been recognized and
107 some of which we cannot do much about when we take note of the need to have large datasets
108 to cover all potential regions of solar wind/magnetosphere parameter space. The noise source
109 in correlative solar wind magnetosphere studies include: instrumental observation errors in
110 interplanetary measurements and in the terrestrial disturbance index or indicator to be
111 predicted; propagation errors between the spacecraft observing the solar wind conditions and
112 the magnetosphere (these include using the correct time lag but, more importantly, spatial
113 structure in interplanetary space that means the solar wind sampled by the spacecraft is not
114 always the same as that which impinges on Earth's magnetosphere); gaps in data sequences;
115 effects of averaging and timescale; non-linear responses of the magnetosphere, pre-
116 conditioning of the magnetosphere and the effects of prior solar wind/magnetosphere coupling
117 history; dipole tilt effects on ionospheric conductivities, magnetospheric structure and current
118 sheets.

119   Hence the effect of adding more terms, even if based on sound physical theory, is not always

120   a positive one. For example, *Lockwood* (2019) showed that although adding the solar wind

121   Poynting flux term does increase the correlation with the geomagnetic *am* index and that the

122   increase for daily or shorter timescales is a small but statistically significant improvement (at

123   over the 3-σ level), the improvement for annual or Carrington rotation means was not

124   statistically significant: hence in the latter cases no statistically significant improvement was

125   achieved, despite the number of free fit variables being doubled from 1 to 2 and the additional

126   term being based on theory.   It should also be noted that the branching ratios used with

127   additive terms can become inappropriate if the coupling function is used outside the

128   conditions that were used to derive them. A common example is averaging timescale which,

129   in general, has different effects on different terms and so the ratio of the two that is

130   appropriate to one timescale does not apply on another. Hence coupling functions with

131   additive terms tend to not be applicable outside the timescale that they were designed for.

132   Table 1 lists a number of coupling functions that have been developed, based on theory and/or

133   empirical fitting (*Balikhin et al.* , 2010; *Bargatze et al* , 1986; *Borovsky,* 2013; *Burton et al.* ,

134   1975; *Cowley* , 1984; *Feynmann & Crooker,* 1978; *Finch & Lockwood* , 2007; *Kan and Lee* ,

135   1979; *Lockwood* , 2019; *Lockwood et al.* , 2014; *Lockwood et al* , 2019a; *Luo et al.* , 2013;

136   *McPherron et al.* , 2015; *Milan et al* , 2012; *Murayama* , 1982; 1986; *Newell et al.*, 2007;

137   *Perreault & Akasofu* , 1978; *Scurry and Russell* , 1991; *Siscoe et al.,* 2002; *Svalgaard &*

138   *Cliver,* 2005; *Temerin & Lee* , 2006; *Vasyliunas et al* , 1982; *Wang et al.,* 2013; *Wygant et al.*,

139   1983). This list is very far from complete, but examples have been chosen to illustrate both

140   the variety and the similarities of proposed formulations, and also some of the principles of

141   the physical theories used to develop them.

142   Table 1 gives the timescale τ on which each coupling function was derived and/or has been

143   tested and/or deployed. It is noticeable that at larger τ, simpler coupling functions have been

144   very successful in yielding very high correlations (*Finch and Lockwood*, 2007). These high

145   correlations are achieved because averaging over long intervals gives cancellation of noise.

146   The averaging timescale of the interplanetary and the terrestrial data that are compared is a

147   crucial consideration because solar wind parameters have a variety of autocorrelation times

148   which means that their distributions of values change with τ in different ways (*Lockwood et*

149   *al.,* 2019a; 2019b). However, this is not often considered when compiling a coupling function

150   and τ is not even explicitly defined in several of the publications (in several cases in Table 1,

151   τ could only be defined from the data plots presented).

152   One idea that has been proposed is that there is a "universal coupling function" that best

153   predicts all terrestrial space weather indices and indicators (*Newell et al.,* 2007, 2008). This

154   idea runs counter to the method now routinely used to reconstruct interplanetary parameters

155   from historic observations of geomagnetic activity. These reconstructions exploit the finding

156   that different geomagnetic indices have different responses to interplanetary parameters and

157   so combinations of them can be used to infer the separate interplanetary parameters. This was

158   inherent in the reconstruction of open solar flux from historic observations of geomagnetic

159   activity by *Lockwood et al* (1999) but first explicitly pointed out and used to extract more than

160   one parameter by *Svalgaard et al.* (2003), who noted that on annual timescales the IMF *B* and

161   solar wind speed V_{SW} could both be derived from any combination of geomagnetic indices

162   that had different dependencies on these two parameters (i.e., different optimum coupling

163   functions). This has been exploited by *Svalgaard and Clive*r (2007), *Rouillard et al.* (2007),

164   *Lockwood et al.* (2009), *Lockwood and Owens* (2011), and *Lockwood et al.* (2014). These

165   methods and results have developed from simple single fits to large ensembles of fits allowing

166   for uncertainties and been reviewed by *Lockwood* (2013). If different indicators of

167   geomagnetic activity have different optimum coupling functions, it means that other space

168   weather activity indicators, such as transpolar voltage, cannot share the same optimum

169   coupling as all, if any, of the geomagnetic activity indices. We here investigate the

170   differences between the optimum coupling functions for transpolar voltage Φ_{PC}, the global *am*

171   geomagnetic index and the nightside northern hemisphere auroral oval index, *AL*. The *am*

172   index has been shown to have the most uniform response to solar wind forcing with Universal

173   Time and time of year by virtue of the relative uniformity of the observing network and its use

174   of area-based weighting functions (*Lockwood et al*., 2019c). However, it has the disadvantage

175   of a time resolution of 3 hours.

176   Table 1 shows that many of the proposed coupling functions predict a role of solar wind

177   number density N_{SW} or mass density $\rho_{SW} = m_{SW}N_{SW}$ (where m_{SW} is the mean ion mass) as

178   contributing to solar wind energy coupling and/or to the driving of magnetospheric

179   convection. For energy considerations, this is mainly because ρ_{SW} and N_{SW} control the

180   dominant (kinetic) energy flux in the solar wind ($\frac{1}{2}\rho_{SW}V_{SW}^{3}$) but it has been shown that solar

181 wind dynamic pressure ($P_{SW} = \rho_{SW}V_{SW}^2$) also has an independent effect (*Lockwood et al.*,

182 2020a; b; c). This is partly through altering the cross-sectional area that the magnetosphere

183 presents to the solar wind flow (*Vasyliunas et al*, 1982) and also via the compression of the

184 near-Earth tail, which enhances the magnetic energy density stored there for a given open

185 magnetospheric flux, thereby enhancing the current in the auroral electrojet of the substorm

186 current wedge when that stored energy is released during a substorm expansion phase (see

187 review by *Lockwood*, 2013). Such a dependence of geomagnetic disturbance in the substorm

188 current wedge region was isolated and identified by *Finch et al.* (2008). This would be in

189 addition to the dependence on ρ_{SW} and V_{SW} due to the energy flux in the solar wind and/or

190 any effect on the magnetic reconnection at the magnetopause which generates the open flux.

191 In addition, the squeezing of the near-Earth tail by P_{SW} would elevate the magnetic shear

192 across the cross-tail current sheet, and hence the total current in that sheet. This could enhance

193 the nightside reconnection voltage Φ_N that closes open field lines. The expanding contracting

194 polar cap (ECPC) model predicts that this would elevate the transpolar voltage Φ_{PC} which is

195 influenced at any one instant by the reconnection voltages in both the dayside magnetopause

196 Φ_D and the cross-tail current sheet Φ_N (*Lockwood, 1991; Cowley and Lockwood*, 1992,

197 *Lockwood and McWilliams*, 2021). However, we need to consider the averaging timescale

198 used, τ. If τ is short compared to the substorm cycle duration we would expect Φ_{PC} to reflect

199 the enhanced Φ_N, and so show some dependence on P_{SW} from this effect of squeezing the tail.

200 On the other hand, if τ is long compared to the substorm cycle duration, the average Φ_N tends

201 to Φ_D and we would therefore expect Φ_{PC} to show only any dependence that Φ_D has on P_{SW}

202 which appears to be considerably smaller (*Lockwood and McWilliams*, 2021).   However, we

203 note that it has long been proposed that P_{SW} has an effect on Φ_D through increasing the

204 magnetic shear across the dayside magnetopause during southward IMF (e.g., *Scurry and*

205 *Russell*, 1991).

206 This discussion of the role of solar wind dynamic pressure is just one example of an important

207 general point – namely that there are a great many processes simultaneously at play in driving

208 the terrestrial space weather response. To allow for these, solar wind coupling functions have

209 evolved away from having theoretically-derived exponents *a*, *b*, *c* and *d* (which were often

210 integers or ratios of integers) to empirically-fitted non-integer values. Hence for the example

211 of P_{SW} effects on the near-Earth tail we do not complicate the coupling function with an

212 additional term or weighting branching ratio, rather we allow the exponents b and c (in the

213 terms $\rho_{SW}{}^b$ and $V_{SW}{}^c$) to vary to allow for such an effect and we would expect such an effect

214 of P_{SW} to raise the exponent b and raise c by twice as much. Hence combinations of

215 mechanisms can be allowed for as long as their effects are multiplicative. To bring theoretical

216 and empirical approaches together, *Borovsky* (2013) used the approach of making a complex

217 theoretical derivation and the reducing to a simple multiplicative form with approximations to

218 derive exponents; however, the uncertainties introduced by any one approximation are not

219 always apparent.

220 There is one last important point to note about coupling functions that is discussed further in

221 the final section of the present paper. None of the forms listed in Table 1 allow for the pre-

222 existing state of the magnetosphere. There are many reasons to expect non-linear

223 magnetospheric responses. For example, the response to a given solar wind forcing quantified

224 by a coupling function will depend on how much open magnetospheric flux already exists at

225 the time but in addition is very likely to also depend on how enhanced the ring current is at

226 the time and/or the state of the mid-tail plasma sheet and cross-tail current sheet. These

227 effects all depend upon the prior history of solar wind-magnetosphere coupling. There are

228 also regular diurnal and annual effects to consider such as dipole tilt effects and seasonal

229 effects in the ionosphere. If they are neglected, all these factors are a source of noise for

230 correlation studies between interplanetary coupling functions and terrestrial disturbance

231 indices.

232 In this paper, we do not attempt to compare the performance of the large number of proposed

233 coupling functions. Such test have been carried out in the past, often as part of an evaluation

234 of a newly-proposed function. Detailed tests against model output were carried out for three

235 coupling functions by *Spencer et al* (2009) and the performance of seven coupling functions

236 in predicting mid-latitude geomagnetic range indices was compared for a range of timescales

237 τ between 1 day and 1 year by *Lockwood and Finch* (2007). *Newell et al.* (2007) compared

238 20 coupling functions against 10 terrestrial indices at hourly resolution.   Rather, we here

239 establish some general principles and apply a generalized common form of coupling function

240 to an unprecedently large dataset containing two different indicators of terrestrial space

241 weather disturbance (the transpolar voltage and two geomagnetic indices) to see if they are

242 significantly different or can be predicted by a common "universal" coupling function.

1-i. Coupling functions based on energy considerations

Lockwood (2019a; b) have shown that the *am, AL* and *SML* geomagnetic indices, which all respond primarily to the substorm current wedge, are well predicted over a range of timescales by the estimated power input to the magnetosphere, P_α (*Vasyliunas et al.*, 1982). This coupling function is given by the product of the dominant energy flux in the solar wind (due to the kinetic energy flux of the particles), the cross-sectional area of the magnetosphere it is incident upon, and a dimensionless transfer function (t_r the fraction of the incident power that crosses the magnetopause into the magnetosphere).

$$P_\alpha = (\rho_{sw} V_{sw}^2)/2) V_{sw} \times (\pi L_o^2) \times t_r \qquad (1)$$

where L_o is the radius of cross-section of the magnetosphere presented to the solar wind flow.

The dayside magnetosphere is assumed to be constant in shape so that $L_o = cL_s$ where $c = L_o/L_s$ is the dayside magnetopause shape factor (assumed constant) and L_s is the stand-off distance of the nose of the magnetosphere which is derived from pressure balance between the geomagnetic field and dynamic pressure of the solar wind, P_{SW} (*Farrugia et al.*, 1989):

$$L_o = cL_s = ck_1(M_E^2/ P_{sw}\mu_o)^{1/6} \qquad (2)$$

where k_1 is the pressure factor for shocked supersonic flow around a blunt nose object, M_E is the magnetic moment of the Earth and μ_o is the permeability of free space (the magnetic constant) *Vasyliunas et al.* (1982) use a dimensionless transfer function of the form:

$$t_r = k_2 \, M_A^{2\alpha} \sin^d(\theta/2) \qquad (3)$$

where the solar wind Alfvén Mach number is $M_A = V_{SW} (\mu_o\rho_{SW})^{1/2}/B$, and k_2 is a constant and α is called the "coupling exponent" that arises from the unknown dependence of t_r on M_A and is the one free fit parameter. θ is the IMF clock angle in the GSM frame of reference. The dependence of t_r on M_A arises from the fact that the dominant energy flux in the undisturbed solar wind, the kinetic energy flux of the particles, is converted into the Poynting flux that enters the magnetosphere by the currents that flow in the bow shock and magnetosheath (*Cowley*, 1991, *Lockwood*, 2004; 2019; *Ebihara et al.*, 2019). From (1), (2) and (3)

$$P_\alpha = k \, B^{2\alpha} \rho_{sw}^{(2/3-\alpha)} V_{sw}^{(7/3-2\alpha)} \sin^d(\theta/2) \qquad (4)$$

270 Where $\{M_E^{2/3}c^2k_1k_2\pi/(2\mu_o^{(1/3-\alpha)})\}$ are rolled into the constant k. However, note that the secular

271 variation in M_E, and hance k, can be allowed for from models of the intrinsic geomagnetic

272 field in long-term reconstructions of space weather conditions (*Lockwood et al.*, 2017).

273 Despite allowing for B, ρ_{SW}, V_{SW} and θ, the coupling function P_α has only the one free fit

274 parameter, the coupling exponent α that arises from an unknown dependence of the transfer

275 function on the solar wind Mach number. This means that P_α is much less prone to overfitting

276 than functions that have separate exponents for the parameters. (Essentially, the exponents of

277 B, ρ_{SW}, V_{SW} are related by the theory, and all are determined by just α).

278 The IMF orientation factor $sin^d(\theta/2)$ was not treated as an independent variable by

279 *Vasyliunas et al.* (1982). However, these authors did outline a test which was used to find

280 that $d = 2$ was the required factor for the optimum (best-fit) α. The same test for other

281 applications of the formulation by *Lockwood et al.* (2019a; b) found a slightly different α (and

282 that it varies with timescale) and this made $d = 4$ marginally better . Table 1 shows that

283 $sin^d(\theta/2)$ is a commonly-used IMF orientation factor for low τ, particularly with $d = 4$.

284 However, a range of d between 1 and 6 has been proposed in the literature. We here note that

285 the test by *Vasyliunas et al.* (1982) has the very important implication that the optimum d is

286 not independent of the other parameters in the coupling function.

287 In their paper, *Vasyliunas et al.* (1982) are somewhat uncertain as to whether they should

288 employ the transverse component of the IMF, $B_\perp$ (the magnitude in the GSM YZ plane) or the

289 full IMF magnitude $B = (B_X^2 + B_\perp^2)^{1/2}$. They found it made only a minor difference in

290 practice but opted to use $B_\perp$ in their text and equations. Their argument was that B_X is not

291 relevant because the field was draped over the nose in the magnetosheath. However, this

292 choice is somewhat inconsistent theoretically because the IMF enters into their coupling

293 function only through the Alfvén Mach number M_A in the interplanetary (unshocked) field

294 and that depends on B and not on $B_\perp$. On the other hand, $B_\perp sin^d(\theta/2)$ is physically

295 meaningful as a way of quantifying the southward component if the IMF in GSM coordinates.

296 **1-ii. Coupling functions based on voltage considerations**

297 In addition to planetary geomagnetic activity, we are aiming to predict transpolar voltage Φ_{PC},

298 we might expect a coupling function based on the interplanetary magnetic field to be more

299   appropriate. Many studies (e.g., *Cowley*, 1984; *Reiff and Luhmann*, 1986), suggest that the

300   transpolar voltage Φ_{PC} is well predicted by the dawn-to-dusk interplanetary electric field

301     $$E_{sw} \; = \; V_{sw} B_S \approx B_\perp V_{sw} sin^d(\theta/2) \qquad\qquad (5)$$

302   Because the voltage applied by the solar wind across the diameter of the magnetosphere is

303     $2L_oE_{SW}$, we can define the reconnection efficiency (the fraction of incident interplanetary field

304   lines captured by magnetopause reconnection) η as

305     $$\eta = \; \Phi_{PC}/(2L_oE_{sw}) \qquad\qquad (6)$$

306   We can then make the same assumption about the dayside magnetopause as was used to

307   generate P_α and again use pressure equilibrium with the solar wind dynamic pressure (*Siscoe*

308   *et al.,* 2002)

309     $$\Phi_{PC} \; = \; 2\eta\, cL_s E_{sw} \; = \; 2\eta\, cE_{sw}\{2kM_E^2/(\mu_o\rho_{sw}V_{sw}^2\}^{1/6} = \eta\, E_{sw}\kappa\{\rho_{sw}V_{sw}^2\}^{-1/6} \quad (7)$$

310   where $\kappa = 2c\{2kM_E^2/\mu_o\}^{1/6}$. From (5), (6) and (7) we have a theoretical prediction of Φ_{PC},

311   which we term Φ_{SW} (the predicted value of Φ_{PC} from solar wind parameters)

312     $$\Phi_{sw} \; = \; \eta\, \kappa\, B_\perp\, \rho_{sw}^{-1/6} V_{sw}^{2/3} sin^d(\theta/2) \qquad\qquad (8)$$

313   Note that the reconnection efficiency η is very unlikely to be a constant. For example,

314   increased solar wind dynamic pressure may increase the magnetic shear across the relevant

315   current shear and various factors may vary the fraction of the dayside magnetopause covered

316   by the magnetopause reconnection X-line (or X-lines) (*Walsh, et al.*, 2017). Hence, we

317   should expect the optimum exponents for B, ρ_{SW} and V_{SW} to differ somewhat from the 1, $-1/6$

318   and 2/3, respectively, predicted by the simple Equation (8).

319   *Borovsky and Birn*, (2014) argue that η is determined by the local Alfvén speeds on the two

320   sides of the magnetopause to the extent that the interplanetary electric field is irrelevant.

321   That being the case any similarity of an empirical coupling function to predict Φ_{PC} and

322   Equation (8) would be a coincidence. From reconnection rate theory and by making

323   approximations *Borovsky and Birn*, (2014) arrive at two distinct coupling functions for

324   predicting dayside reconnection voltage here termed Φ_{BB}. The sharp transition point between

325   the two regimes where these apply is solar wind Alfvén Mach number, $M_A \approx 6$. For $M_A < 6$

326   they find the approximate form $B^{0.51}N_{sw}{}^{0.24}V_{sw}{}^{1.49}\ sin^2(\theta/2)$ and for $M_A > 6$ they find the

327   approximate form $B^{1.38}N_{sw}{}^{-0.19}V_{sw}{}^{0.62}\ sin^2(\theta/2)$.

328   **1-iii. Coupling functions from empirical fits**

329   Like many of the papers listed in Table 1, we here make empirical fits using a general form of

330   coupling function C_f, given by

331     $$C_f\ =\ B_{\perp}^{a}\ \rho_{sw}^{b}\ V_{sw}^{c}\ sin^d(\theta/2) \qquad\qquad (9)$$

332   This general form which can reproduce P_α (for $a = 2\alpha$, $b = 2/3-\alpha$, and $c = 7/3- 2\alpha$), E_{SW}

333   (for $a = 1$, $b = 0$ and $c = 1$) , Φ_{SW} (for $a = 1$, $b = -1/6$, and $c = 2/3$) as well as Φ_{BB} (for $M_A < 6$

334     $a = 0.51$, $b = 0.24$, and $c = 1.49$ and for $M_A > 6$, $a = 1.38$, $b = -0.19$, and $c = 0.62$). As

335   shown by Table 1, this form also encompasses a wide variety of the proposed empirical

336   coupling functions.   Note that this form could also reproduce the often-used "epsilon" factor,

337   ε, (for which $a = 2$, $b = 0$ and $c = 1$) but that is not considered further in this paper because ε is

338   based on the incorrect assumption that the relevant energy flux in the solar wind is the

339   Poynting flux (see *Lockwood*, 2013; 2019) and, although this can be made consistent with

340   other energy coupling functions such as P_α (that is correctly based on the dominant solar wind

341   kinetic energy flux) this is only achieved using an extreme value of unity for the coupling

342   exponent α, and this does not agree at all with experimental estimates. This theoretical flaw

343   is the reason why ε performs considerably less well than P_α on all averaging timescales (see

344   *Finch & Lockwood*, 2007).

345   It should be noted that not all proposed coupling functions, not even all the simple ones, fit

346   the general formulation given in Equation (9), particularly those that employ additive terms.

347   For example, *Boyle et al* (1977) propose the use of $10^{-4}V_{SW}{}^2 +11.7B\ sin^3(\theta/2)$ to predict Φ_{PC},

348   which it does exceptionally well: the reasons for its success will be analyzed later in this

349   paper.   In general, the problem with additive terms is that, unless each term is describing a

350   distinct physical mechanism, they are purely numerical fits to the available data. Adding

351   terms until a fit is achieved without a theoretical basis does makes the risk of overfitting

352   considerably greater: essentially one can fit any time series with combinations of other time

353   series if one is free to select enough of them until a fit is obtained. Physics-based coupling

354   functions are usually fundamentally multiplicative in form although some factors can be

355 broken down into the sums of additive terms for theoretical reasons (e.g., *Borovsky*, 2013;

356 *Lockwood*, 2019; *Newell et al*, 2008).

357 The next section describes how there are a number of procedural issues to resolve for studies

358 using even the relatively simple form of coupling function generalized by Equation (9). For

359 this reason, in the present paper we do not extend the present study to formulations involving

360 additive terms.

1-iv. Frequently neglected factors in deriving coupling functions

362 There are a number of factors that have often been neglected when deriving coupling

363 functions, the most important being: (i) the effect of data gaps; (ii) the effects of data

364 averaging; (iii) the effect of the number of datapoints available; (iv) the differences between

365 the various terrestrial space weather indicators; (v) overfitting; (vi) non-linearity and pre-

366 conditioning of the magnetosphere; (vi) other sources of noise such as measurement errors,

367 propagation lags, spatial structure in interplanetary space (which can mean that the solar wind

368 hitting Earth differs from that measured at the upstream spacecraft), seasonal and other dipole

369 tilt effects. We address just some of these in this paper. The effect of data gaps was studied

370 by *Lockwood et al.* (2019a) who introduced synthetic gaps at random (but to give the same

371 distribution of durations as has occurred for early interplanetary observations) into continuous

372 and near-continuous data and studied the errors introduced. These errors were not only in the

373 greater uncertainty of one individual fit, but also in systematic deviations in the means and

374 modes of the distributions of ensembles of many fits. It is often assumed that the effect of data

375 gaps averages out, but this is not the case: data gaps introduce noise into the correlation

376 studies and fitting procedures, facilitating overfitting which generates both random and

377 systematic errors.

378 Correlations of coupling functions with terrestrial space weather indicators naturally increase

379 with increased averaging timescale τ because the noise in both time series is increasingly

380 averaged out (*Finch and Lockwood*, 2007). However, there are problems associated with

381 averaging high-resolution interplanetary field data in relation to the IMF orientation and these

382 are often not addressed. *McPherron et al* (2015) correctly used hourly data which they

383 obtained by passing 1-minute data through low-pass filter by taking a 61-point running

384 average and resampled every hour to obtain centered hourly averages. They note that this

385   improves the hourly-average coupling functions by eliminating nonlinearities resulting from

386   the use of hourly averages of IMF components in calculating the transverse component $B_\perp$

387   and the clock angle θ. This is certainly true and in the next section we investigate how good

388   this procedure is and why it is needed. We also point out there is a second issue to consider

389   about the effects of data averaging.

390   **1-v. The effect of averaging procedure**

391   The magnetosphere responds to integrated forcing (*Lockwood et al.*, 2016). For example, if

392   we have a terrestrial indicator that responds to the energy input into the magnetosphere and a

393   coupling function that quantifies that energy input, over a period τ we require the total of that

394   energy input. Similarly, for any empirical coupling function C_f (equation 9) we want the

395   integrated solar wind forcing over the time. By the definition of the arithmetic mean, this

396   means we need a coupling function for the interval τ given by

397    $$(1/\tau)\int_0^\tau C_f\, dt \ = \ <C_f>_\tau \ = \ < B_\perp^a\, \rho_{sw}^b\, V_{sw}^c\, sin^d(\theta/2) \ >_\tau \qquad (10)$$

398   Where the values C_f, $B_\perp$, ρ_{SW}, V_{SW} and θ are all values from high-time resolution

399   measurements. However, this has usually in the past been approximated using the seemingly

400   similar value

401    $$[C_f]_\tau \ = \ < B_\perp >_\tau^a .< \rho_{sw} >_\tau^b .< V_{sw} >_\tau^c .< sin(\theta/2) >_\tau^d \qquad (11)$$

402   And in many cases the average clock angle has been computed from the means of the IMF *Y*

403   and *Z* components so $[\theta]_\tau$ is used for θ and $<B_\perp>_\tau$ is replaced by $[B_\perp]_\tau$, where

404    $$[\theta]_\tau \ = \ tan^{-1}(|<B_Y>_\tau|/<B_z>_\tau) \qquad (12)$$

405   as is the transverse IMF component

406    $$[B_\perp]_\tau \ = \ (<B_Z>_\tau^2 + <B_Y>_\tau^2)^{1/2} \qquad (13)$$

407   This generates a coupling function that we denote as $[C_f{}^*]_\tau$ that has two separate problems.

408   The first of these problems was addressed by the averaging procedure for $B_\perp$ and θ that was

409   adopted by *McPherron et al.* (2015) who evaluated both at high time resolution before

410   averaging and avoided using wither $[\theta]_\tau$ and $[B_\perp]_\tau$ (this is hereafter referred to as the *MEA15*

411   procedure and is what we will use in later sections). In Figure 1 we highlight its importance

412 but also deconvolve it from a second effect. Note that same operations are used in generating

413 $< C_f >_\tau$, $[C_f]_\tau$ and $[C_f*]_\tau$ - the difference between them is purely the order in which they are

414 carried out: $< C_f >_\tau$ can be characterized as the parameters being "combined-then-averaged" ,

415 whereas for $[C_f]_\tau$ and $[C_f *]_\tau$ they are "averaged-then-combined". (The difference between

416 $[C_f]_\tau$ and $[C_f *]_\tau$ is that for the latter "averaged-then-combined" is even applied to the

417 derivations of clock angle θ and transverse magnetic field, $B_\perp$).

418 Figure 1a demonstrates that it is not a valid assumption to take $< C_f >_\tau$ and $[C_f *]_\tau$ to be the

419 same, using the example of the *Vasyliunas et al.* (1982) energy transfer coupling function P_α

420 for a coupling exponent $\alpha = 1/3$ (hence this P_α is an example of C_f with $a = 2/3$, $b = 1/3$, $c =$

421 $5/3$ and we here have used $d = 4$). The specific exponents do not change the general

422 principles demonstrated by Figure 1.   The raw data in Figure 1 are all the 9,930,183 valid 1-

423 minute resolution values of P_α and all the 11,646,678 valid 1-minute resolution values of the

424 IMF clock angle θ and tangential field $B_\perp$ available from the Omni2 dataset for 1995-2020,

425 inclusive (*King and Papitashvili,* 2005). This interval is used because data gaps are both

426 much rarer and shorter than before 1995 because of the advent of the Wind, Advanced

427 Composition Explorer (ACE) and Deep Space Climate Observatory (DSCOVR) spacecraft

428 (*Lockwood et al.,* 2019a).   The averaging time in this example is $\tau = 1$ hr. Figure 1a

429 compares $< P_\alpha >_\tau$ and $[P_\alpha*]_\tau$ and the linear correlation coefficient between the two is very

430 poor indeed, being just 0.26.   Note in Figure 1a both $< P_\alpha >_\tau$ and $[P_\alpha*]_\tau$ have been

431 normalized by dividing by P_o, the overall mean of P_α: this has the advantage of cancelling out

432 all the constants in the theoretical derivation of P_α. Rather than presenting scatter plots with

433 massively overplotted points, Figure 1 employs data density plots with the fraction of

434 samples, $n/\Sigma n$, color-coded with n being the number of sample pairs in small bins. In Figure

435 1a there are 100 bins of width 0.08 for both axes. Figure 1b identifies why the agreement in

436 Figure 1a is so poor: it is for G, which is C_f (in this case is P_α) without the IMF orientation

437 term, i.e.

438 $$G = C_f/F(\theta) = C_f/sin^4(\theta/2) = B_\perp^a \, \rho_{sw}^b \, V_{sw}^c \qquad (14)$$

439 This is a factor that we will use again later in deriving optimum values for the exponent d.

440 Figure 1b compares the combine-then-average values and the average-the-combine values for

441   G (for the same example as shown in Figure 1a and in the same format), $<G>_\tau$, with a

442   corresponding average-then-combine value $[G]_\tau = <B_\perp>^a <\rho_{SW}>^b <V_{SW}>^c$: again, all values

443   have been normalized by dividing by the overall mean, G_o. Note that we here use $<B_\perp>^a$ and

444   not $[B_\perp]_\tau^a$ (where $[B_\perp]_\tau$ is defined by Equation 13) – in other words we have moved to the

445   *MEA15* procedure in order to remove the component-averaging effect on $B_\perp$ (and θ is not a

446   factor in G). The agreement is here is very good indeed, with values close to the diagonal

447   line.

448   However, the agreement in Figure 1b is still not quite perfect. Small differences remain

449   because of the difference between "Hölder means" (or a "power means") $[<X^p>_\tau]^{1/p}$ of a

450   general variable X and the corresponding arithmetic means $<X>_\tau$ and hence between $<X^p>_\tau$

451   and $<X>_\tau^p$. Figure 1b shows these differences are very small indeed for the variables X, the

452   exponents p and the timescales τ involved in G in the example shown in Figure 1and can be

453   neglected. However, in general, arithmetic and Hölder means are related by what is called

454   the "Hölder path" which results in the Hölder mean increasing with p (the arithmetic mean

455   being the Hölder mean for the special case of $p = 1$). From comparison of Figures 1a and 1b,

456   we know that the poor correlation in Figure 1a must be arising from the IMF orientation term,

457   $F(\theta)= sin^4(\theta/2)$ and/or not using the *MEA15* procedure to averaging of $B_\perp$. Figure 1c

458   compares the combine-then-average values of the clock angle θ, $<\theta>_\tau$ with the average-then-

459   combine value, $[\theta]_\tau$, given by equation (12), in the same format as Figure 1a (for bins of

460   2°×2°) and although a great many points line up along the diagonal, there is considerable

461   spread, especially at θ near zero or 180° (strongly northward and strongly southward IMF,

462   respectively). Figure 1d makes the same comparison for the transverse field estimate, $B_\perp$.

463   Note that if we use the IMF magnitude B instead of $B_\perp$ in the coupling function, this effect

464   does not arise; however, as found by *Vasyliunas et al* (1982), tests show that using $B_\perp$ usually

465   results in somewhat higher correlations. Figure 1e is for the same comparison for $sin^4(\theta/2)$

466   and the spread is greatest at the southward IMF end of the range.

467   Figure 1f demonstrates that the *MEA15* averaging essentially removes all problems associated

468   with $B_\perp$ by avoiding $[B_\perp]_\tau$. However, Figure 1g shows that a problem still remains with the

469   clock angle term $sin^4(\theta/2)$. This is because the arithmetic and Hölder means are appreciably

470   different for this parameter. There is still a good correlation in Figure 1g and many of the

471   points line up along the ideal diagonal: hence it is tempting to say this is just one more (small)

472   source of noise and so it is valid to use $<sin(\theta/2)>^d$ instead of $<sin^d(\theta/2)>$. However, there

473   is a subtle point here: the spread shown in Figure 1g increases with d because the difference

474   between arithmetic and power means increases with exponent. Hence using $<sin(\theta/2)>^d$

475   discriminates against higher d by introducing more noise and so such studies will tend to

476   derive a value for d that is too low.

477   We can understand why the IMF orientation term is so different to the other three by looking

478   the variability of the various factors within the averaging period. Figure 1 of *Lockwood et al.*

479   (2019a) showed that the autocorrelation time of the IMF orientation is considerably shorter

480   than for the other parameters and so most of the variability of P_α on sub-hour timescales

481   originates from the IMF orientation term. This is true for all coupling functions. If a

482   parameter X is constant over the averaging time, then both the Hölder mean $[<X^p>_\tau]^{1/p}$ and

483   the arithmetic mean are equal to that constant value of X and $<X^p>_\tau = <X>_\tau^p$. On the other

484   hand, if X varies a great deal during the averaging interval, then the Hölder mean is

485   greater/smaller than the arithmetic mean for p greater/smaller than unity. Hence the much

486   greater variability in the IMF orientation is the reason why it behaves so differently.

487   (However, note that if we increase the averaging timescale τ, the other parameters will also

488   start to suffer from the same problem as the clock angle term).

489   We can conclude, the often-used average-then-combine procedure generates large errors for

490   the IMF orientation terms in deriving an empirical coupling function C_f, even for $\tau = 1$ hr.

491   The *MEA15* averaging procedure removes a great deal of the problem (at last for $\tau = 1$ hr), but

492   a second error (due to the difference between Hölder means and arithmetic means) remains

493   for the clock angle term.   This generates a problem when using an iterative procedure, such

494   as the Nelder-Mead simplex search method used here (*Nelder and Mead*, 1965; *Lagarias et*

495   *al.,* 1998) to fit the exponents a, b, c or d. This is because of the need to compute the mean of

496   the combination of the samples (and in the dataset used in Figure 1 there are 9,930,183 valid

497   1-minute samples of P_α) at the start of every round of the iteration. We have achieved this in

498   some cases, but it takes enormous amounts of computer time and sometimes fails to converge.

499   Fortunately, Figure 1 points to a compromise. It suggests we can use a hybrid approach of

500   using $<B_\perp>^a$, $<\rho_{SW}>^b$, and $<V_{SW}>^c$, but must use $< sin^d(\theta/2)>$ for the IMF orientation term.

501   This yields a mean coupling function estimate for averaging time τ of

502 $$[C'_f]_\tau \ = <B_\perp>_\tau^a.<\rho_{sw}>_\tau^b.<V_{sw}>_\tau^c.<sin^d(\theta/2)>_\tau \qquad (15)$$

503   Figure 1h compares $<P_\alpha>_\tau$ and $[P'_\alpha]_\tau$ and it shows that agreement is very good with all

504   points lying close to the diagonal line and the correlation coefficient is 0.997. We have

505   repeated this test for all permutations of the maximum and minimum estimates of the

506   exponents a, b, c and d derived here and it is always valid to this level for $\tau = 1$ hr. Equation

507   (15) is practical for use in an iterative fit procedure because for a given d we can compute

508     $<B_\perp>_\tau$, $<\rho_{SW}>_\tau$, $<V_{SW}>_\tau$, and $<sin^d(\theta/2)>_\tau$ just once before each iteration and then readily

509   iterate a, b, and c to the optimum fit using the Nelder-Mead simplex search. This can then be

510   repeated for different values of d. We have carried out some sample tests of our analysis that

511   compared the results of fits using the ideal mean $<C_f>_\tau$ and our pragmatic hybrid solution,

512     $[C'_f]_\tau$ and the results were almost identical. However, we were limited in the number of

513   these tests that we could carry out by the extremely large compute time caused by the need to

514   average the whole dataset at each iteration step to define the exponents when using $<C_f>_\tau$.

515   We have repeated all calculations using the average-than-combine procedure, $[C_f]_\tau$ (but

516   using the *MEA11* procedure for $B_\perp$ and θ to avoid $[\theta]_\tau$ and $[B_\perp]_\tau$) and, as described later, the

517   fits obtained were always poorer because of the effect highlighted in Figure 1g.

518   **2. Data Employed**

519   We use the dataset of hourly mean transpolar voltage Φ_{PC} observed over the years 1995-2020

520   (inclusive) by the northern-hemisphere SuperDARN array of coherent-scatter HF radars, as

521   described by *Lockwood and McWilliams* (2021). These hourly data are means of 30, 2-minute

522   integrations. We adopt the requirement that the hourly mean of the number of radar echoes

523   available, n_e, exceeds a minimum value $n_{lim} = 255$. This threshold was derived by *Lockwood*

524   *and McWilliams* (2021) as the optimum compromise between having enough echoes that the

525   influence of the model used in the "map-potential" data-assimilation technique is small, but

526   not so large that the distribution of Φ_{PC} values is greatly distorted by the loss of low-flow,

527   low-n_e samples. *Lockwood and McWilliams* (2021) also found that this threshold gave peak

528   correlation between the radar Φ_{PC} estimates and those from nearby passes of low altitude

529   polar-orbiting spacecraft. The condition that $n_e > n_{lim} = 255$ yields a total of 65,133 Φ_{PC}

530   samples in the dataset.

531   We wish to compare the optimum coupling function for the global parameter Φ_{PC} with that

532   for global geomagnetic activity. We here use the *am* geomagnetic index (*Mayaud*, 1980) and

533   the *AL* auroral electrojet index (*Davis and Siguira*, 1966). The *am* index has the most uniform

534   network, in both hemispheres, of observing stations and uses weighting functions to yield the

535   most uniform response possible to solar wind forcing with Universal Time and time of year

536   (*Lockwood et al.*, 2019c). The *am* index is based on the range of variation of the horizontal

537   field component in 3-hour windows. To get a data series that is simultaneous with the Φ_{PC}

538   data, we here linearly interpolate the 3-hourly *am* values to the mid-points of the hours used to

539   generate the Φ_{PC} data. This is only done for the Φ_{PC} samples that meet the $n_e > n_{lim} = 255$

540   criterion and so we end up with a dataset of 65,133 interpolated *am* samples that are

541   simultaneous with the Φ_{PC} data. The advantage of using *am* is that it is the geomagnetic index

542   that is by far the most free of seasonal and hemispheric effects which introduce noise in

543   correlation studies, and it is genuinely global. The disadvantage is that it is 3-hourly and the

544   interpolated values will reflect this timescale. We also compare with simultaneous hourly

545   means of the *AL* index, by averaging one-minute values over the same hour as used to average

546   the radar data. Note that *AL* comes from northern hemisphere stations and so contains an

547   annual variation caused by seasonal changes in ionospheric conductivities: this is an

548   additional noise factor for correlative studies that could potentially be reduced using a model

549   of the effect of the conductivities.

550   Figure 2 compares these hourly datasets of Φ_{PC} , *am* and *AL* by presenting data density plots

551   of the normalized geomagnetic indices (the *am* index in Figure 2a, *am*/<*am*> and the *AL* index

552   in Figure 2b, *AL*/<*AL*> where the means are taken over the whole dataset) as a function of the

553   simultaneous normalized transpolar voltage, Φ_{PC} /<Φ_{PC} >. In both cases, means of the

554   normalized geomagnetic index (with error bars between the 1-sigma points of the distribution)

555   are also plotted for coarser bins Φ_{PC} /<Φ_{PC} >. Figure 2a shows that the *am* index is, on

556   average, close to proportional to Φ_{PC}, but with considerable scatter. This proportionality of

557   mid-latitude range indices and transpolar voltage, such as *am* and *kp*, has been discussed by

558   *Thomsen* (2004). The variation of *AL* with Φ_{PC} is a bit more complex with only a small

559   increase at Φ_{PC} /<Φ_{PC} > below about 0.5 (i.e., Φ_{PC} below about 20 kV), above which *AL*

560   increases in magnitude more rapidly with Φ_{PC} than does *am*. The scatter is higher for *AL*

561   because it contains noise associated with the seasonal variation in ionospheric conductivities.

562   In contrast, *am* has very little such noise, being compiled from matching rings of stations in

563   both hemispheres (and using weighting functions to account for any inhomogeneity) and has

564   been shown to have an extremely flat response (in both *UT* and time of year to solar wind

565   forcing as a result (*Lockwood et al.,* 2019c).

566   To derive the coupling functions, we use 1-minute resolution averages of the Omni dataset of

567   near-Earth measurements of interplanetary space (*King and Papitashvili,* 2005). From this we

568   generate running means using one-hour (61-point) boxcar averages of $B_\perp$, ρ_{SW}, V_{SW}, and

569    $sin^d(\theta/2)$ for the value of d we are investigating (the using the *MEA15* averaging procedure).

570   Mean values are only considered valid when the number of samples is large enough to make

571   the error in the mean less than 5%, thresholds that were determined by *Lockwood et al.*

572   (2019a) for each parameter by the random removal of 1-minute samples from hourly intervals

573   for which all 60 samples were available: because of its very low acfs, the most stringent

574   requirement is set by the IMF orientation factor which requires 82% of samples (i.e., 43 out of

575   the 60). The averaging generates a sequence of hourly running means that are 1 min apart.

576   We combine these into mean coupling function $[C'_f]_{1hr}$ using our hybrid averaging formula

577   (Equation 15). For test purposes only we also generate $[C_f]_{1hr}$ using the average-then-combine

578   procedure (equation 11, with *MEA15* averaging to generate hourly means of θ and $B_\perp$). We

579   then select the value at each time of the transpolar voltage and *am* dataset, allowing for the

580   appropriate propagation lag, δt_p.

581   To determine the required propagation lags we make the initial assumption that the IMF

582   orientation factor is $sin^3(\theta/2)$ (i.e., $d = 3$), although this is refined in Section 3 of this paper.

583   We have carried out a sensitivity test to show that this choice does not influence the optimum

584   derived lags. The Omni data have been propagated from the point of observation to the nose

585   of the magnetosphere (*King and Papitashvili,* 2005): any variable error in that propagation

586   will be a source of noise in our correlation studies. We then add a lag δt to allow for

587   propagation across the magnetosheath to the dayside magnetopause and then to the relevant

588   part of the ionosphere. We then vary δt between −60 min (unphysical) and +120 min and for

589   each lag evaluate the linear correlation coefficients between Φ_{PC} and *am* and the optimum

590   coupling function, C_f (for the assumed value for d of 3). Note that here and hereafter we refer

591   to the hourly coupling function generated by our hybrid averaging procedure, $[C'_f]_{1hr}$ as just

592   C_f, unless we are making a comparison with the results of the often-used average-then-

593 combine procedure, in which case we distinguish between $[C'_f]_{1hr}$, $[C_f]_{1hr}$ and $[C_f*]_{1hr}$. We

594 want C_f to be linearly related to the terrestrial activity indicator and so we maximise the linear

595 correlation coefficient, r. The exponents a, b, and c at each δt were determined using the

596 Nelder-Mead simplex method to minimize $(1-r)$ (*Nelder and Mead*, 1965; *Lagarias et al.,*

597 1998). From this the optimum exponents a, b, and c (for the assumed $d = 3$) and the

598 correlation coefficient r were determined at each lag δt.

599 The lag correlograms, $r(\delta t)$ obtained this way are shown in the top panel of Figure 3: mauve is

600 for Φ_{PC}, the blue is for the interpolated *am* and the green is for *AL*. The vertical dashed lines

601 mark the lags δt_p giving peak correlation. The bottom panel shows the best-fit exponents a, b,

602 and c as a function of lag δt: it can be seen that they do vary somewhat with δt but only to a

603 small extent around the optimum lags. δt_p. From Figure 3, we determine the optimum lags are

604 $\delta t_p = 18.5$ min for Φ_{PC}, $\delta t_p = 30.5$ min for *am* and $\delta t_p = 45.5$ min for *AL*. Note that the much

605 greater persistence in the plot for *am*, because of it is interpolated from 3-hourly data, and this

606 makes the peak for *am* lower and broader. The survey of the Φ_{PC} dataset by *Lockwood and*

607 *McWilliams* (2021) demonstrates how Φ_{PC} responds to both the reconnection rate at the

608 dayside magnetopause Φ_D and reconnection in the cross-tail current sheet tail Φ_N (a good

609 proxy for which is the *AL* auroral electrojet index), as predicted by the ECPC model

610 (*Lockwood*, 1991; *Cowley and Lockwood*, 1992). Indeed, in the approximation that the polar

611 cap remains circular at all times, Φ_{PC} is the average of Φ_D and Φ_N (*Lockwood, 1991).*

612 *Lockwood and McWilliams* (2021) show that for low $-AL$, the lag of Φ_{PC} after solar wind

613 forcing is about 5 min, which is consistent with the expected response delay of Φ_D, but the lag

614 of the *AL* response (and hence inferred Φ_N) is 35 min, similar to the lag for *am* that is derived

615 here. Hence we would expect the average lag for Φ_{PC}, which is generated by a combination

616 of Φ_D and Φ_N, to be around 20 min., as is indeed found to be the case in Figure 3. However,

617 we note that there is considerable variability in the lags connected with Φ_N, partly because of

618 the variability in substorm growth phase duration (*Freeman and Morley*, 2004; *Li et al.*, 2013)

619 but also because, depending on the onset location, the precipitation in the initial part of the

620 expansion phase can suppress ionospheric flow by enhancing conductivity, giving an addition

621 delay in the appearance of the full voltage due to Φ_N (*Grocott et al.*, 2009).

622   The optimum coupling exponents at these lags are $a = 0.672$, $b = 0.017$ and $c = 0.561$ for Φ_{PC}

623   and $a = 0.802$, $b = 0.360$ and $c = 2.566$ for *am* (for this d of 3). The uncertainties in these

624   values and their dependence on d will be evaluated later. The gray areas in Figure 3 define

625   the 1-σ, 2-σ and 3-σ uncertainties in the δt_p estimates. These are evaluated by looking at

626   the significance S of the difference between the correlation at a general lag $r(\delta t)$ and its peak

627   value at the optimum lag δt_p (where $r = r_p$) where $S = 1-p$, and p is the probability of the null

628   hypothesis that r and r_p are actually the same. S is computed using the Meng-Z test (*Meng et*

629   *al.,* 1992) for the significance of the difference between correlation r_{AB} (between two

630   variables A and B) and r_{AC} (between A and C) allowing for the fact that B and C may be

631   correlated ($|r_{BC}| > 0$). S is, by definition, zero at the optimum lag δt_p, and the 1-σ, 2-σ and 3-σ

632   uncertainties are the lags at which S has risen to 0.68, 0.95 and 0.997, respectively. For Φ_{PC}

633   the 2-σ uncertainty band is between 17.2 min. and 19.8 min.; for *am* it is between 26.5 min.

634   and 34.5 min. and for *AL* it is between 38.5 and 52.5 min. Note that these uncertainties are

635   smaller than in many studies because the number of samples is so large. Because Figure 3

636   was generated using an assumed value of $d = 3$, it was repeated for a range of selected values

637   of d between 1 and 7 (which section 3-ii shows covers the range of interest), the differences

638   between the derived optimum lags were always considerably smaller than the above 2-σ

639   uncertainties.

640   **3. The IMF orientation factor**

641   As discussed by *Vasyliunas et al*. (1982), the optimum IMF orientation factor is not

642   independent of the other fit exponents. In addition, Section 1-v has described how, because its

643   much greater rapid variability, we have to deal with it differently when generating average

644   coupling functions. Section 3-i discusses the distributions of IMF orientation factors before

645   in Section 3-ii we evaluate the optimum values of d for Φ_{PC}, *am* and *AL*.

646   **3-i. Occurrence distributions of IMF orientation factors and the effect of averaging**

647   **timescale**

648   Figure 4 shows the distributions of various parameters relevant to the IMF orientation factor,

649   all panels being for 1-minute integrations of data and in the Geocentric Solar Magnetospheric

650   (GSM) frame of reference. This Figure is for 11,646,678 1-minute Omni data samples from

651   1995-2020, inclusive. The vertical axis is the fraction of samples $n/\Sigma n$ in 100 bins of width

652   that are 1% of the range of the horizontal axis. The sequence of Figures 4a-4e are from

653   *Lockwood et al.* (2019b) and explain how strange, highly-asymmetric distributions of 1-

654   minute samples of the various coupling functions come about from a near-Gaussian

655   distribution of the IMF B_Z component, which is very close to symmetric around zero, and a

656   double-peaked distribution of the IMF B_Y component, which is also very close to symmetric

657   around zero. As discussed above, the most commonly-adopted form of the IMF orientation

658   factor has been $sin^d(\theta/2)$ with $d = 4$ although a range of d from 1 to 6 has been proposed.

659   Figure 4f shows that $d = 2$ yields a symmetric distribution around an average of 0.5 with

660   dominant isolated peaks in the bins closest to 0 and 1. On the other hand, Figure 4g shows

661   that $d = 4$ yields a highly asymmetric distribution with an even-larger isolated peak in the bin

662   nearest 0 and only a very small one in the bin nearest 1. The peak in the lowest bin is even

663   larger for $d = 6$, shown in mauve in Figure 4h and larger again for two other commonly used

664   "half-wave rectified" IMF orientation factors B_S in green (where $B_S = -B_Z$ for $B_Z < 0$ and $B_S =$

665   0 for $B_Z \geq 0$) and $U(\theta)cos(\theta)$ in blue (where $U(\theta) = 0$ for $\theta < 90°$ and $U(\theta) = -1$ for $\theta \geq 90°$).

666   The distributions for B_S and $U(\theta)cos(\theta)$ are very similar because $U(\theta)cos(\theta) = B_S/B$ and the

667   factor 4.5 is used to display B_S on the same scale in Figure 4h because it makes the mean

668   value the same as for $U(\theta)cos(\theta)$ and very similar to that for $sin^6(\theta/2)$.

669   These strange distributions of IMF orientation factors have great significance for statistical

670   studies of the performance of a proposed coupling function because they determine the

671   weighting given to a given clock angle θ in a correlation study. This means that when we

672   alter d, we are not just investigating the how the IMF orientation influences solar wind-

673   magnetosphere coupling, we are also changing the statistical weighting given to certain IMF

674   orientations in our correlation studies. For B_S and $U(\theta)cos(\theta)$ the value is zero for 50% of

675   the dataset (for $B_Z > 0$) and so the coupling function is strongly weighted to accurate

676   prediction of quiet times, which is probably not what is wanted in many applications. Figure

677   4h shows the distribution is not quite so extreme for $sin^6(\theta/2)$, but it has the same basic form.

678   As we reduce d, that weighting shifts until for $d = 2$ the distribution is dominated by two

679   equal peaks close to due northward and close to due southward IMF. For $d = 1$ (Figure 4e) it

680   is dominated by close to purely southward IMF. The key point is that the choice of the IMF

681   orientation factor is also setting the weighting given to certain data in the statistical fit of the

682   coupling function if we use a fit-quality metric such as correlation coefficient or root-mean-

683   square deviation.

684   Figure 1 of *Lockwood et al.* (2019a) shows why the IMF orientation factor has a key role in

685   setting the variability of a coupling function. It is because its autocorrelation function (acf)

686   falls much more rapidly with time lag for any other solar wind parameter. For a lag of 1 hour,

687   the acf for $sin^4(\theta/2)$ in near-Earth space is 0.45, whereas for the solar wind number density

688   N_{SW} it is 0.88, for the IMF B it is 0.93 and for the solar wind speed V_{SW} is 0.99. Hence short-

689   term variability of a coupling function is set by that in the IMF orientation factor whereas, as

690   shown below, this factor essentially becomes constant at timescales of a year or more. This

691   exemplifies the general fact that the IMF orientation factor distribution depends critically on

692   averaging timescale which is here illustrated by Figure 5 for the commonly adopted $sin^4(\theta/2)$

693   factor. We take running boxcar (running) means of the 1-minute data over intervals τ and

694   deal with data gaps by only retaining averages that are made up of a fraction of the potential

695   maximum number samples that exceeds $f(\tau)$, the minimum needed to keep errors due to data

696   gaps below 5%. The minimum fractions $f(\tau)$ needed were computed by introducing random

697   synthetic data gaps into continuous IMF data, computing the error caused and repeating 10

698   times for each hourly mean, as carried out for $\tau = $ 1hr by *Lockwood et al.* (2019a). For

699   example, Figure 1b of *Lockwood et al.* (2019a) shows that we require $f(\tau) > 0.82$ to keep

700   errors in the hourly mean IMF orientation factor to below 5%. At very large τ it becomes

701   very hard to find intervals with no data gaps; however, $f(\tau)$ falls with τ and so for $\tau > 1$ day

702   we use the $f(\tau)$ value for 1 day.

703   As τ is increased, the central limit theorem (*Fischer*, 2010) applies and the distribution of any

704   parameter narrows towards a delta function at the overall mean (i.e., the value derived for a τ

705   equal to the duration of the whole dataset). However, because of the unusual form of the

706   distribution at $\tau = $ 1min., the distribution for $sin^4(\theta/2)$ evolves through a series of forms and

707   how it does so is determined by the timescales of the variability in the IMF orientation. For τ

708   = 15 min. the distribution is quite similar to that for $\tau = $ 1 min., but the peak at $sin^4(\theta/2) = 0$

709   has diminished and more samples occur at larger values. For $\tau = $ 1 hr (the timescale used in

710   this paper), this results in a near-linear distribution, but still with a pronounced peak at 0. By τ

711 = 6 hr the distribution has evolved into very close to a lognormal form and by $\tau = 1$ day it is

712 close to a Gaussian form that is symmetrical about the overall mean value (the mauve vertical

713 dashed line). Further increases in τ cause the width of the distribution about the overall mean

714 to decrease. For $\tau = 1$ year, the distribution is narrow and hence the IMF orientation factor

715 can, to within a reasonably small error, be taken to be constant. This is why successful

716 coupling functions at annual timescales usually do not contain a factor that allows for IMF

717 orientation. Note that all parameters in a coupling function, not just the IMF orientation,

718 follow the central limit theorem, but the other factors tend to start (for 1-minute observations)

719 from a log-normal form and then evolve into the narrowing Gaussian and do not start from the

720 unusual distributions for the IMF orientation factors (*Lockwood et al.,* 1999a; b).

721 The averaging timescale τ has significance on two levels. Here we study it purely in the

722 context of averaging data and the changes of the distribution that are associated with the

723 reduction in noise brought about by the averaging. However, it should be noted that τ also

724 has significance on a physical level. This is because the IMF orientation in the upstream solar

725 wind will be influenced by the passage of the solar wind through the bow shock and

726 magnetosheath and there will be timeconstants for changes in the coupling of energy, mass

727 and momentum from the near-magnetopause sheath into the magnetosphere (e.g., changes in

728 the reconnection rate and in the X-line latitude and orientation). These will almost certainly

729 act as a low-pass filter on the IMF orientation variations, but it is not yet clear what averaging

730 timescale τ will best mimic the effects of this low-pass filter and how it might vary with solar

731 wind conditions. The optimum τ will depend on the terrestrial parameter considered. For

732 example, studies using ground-based radars show rapid responses in ionospheric flows and

733 the location of the inferred open/closed boundary in the cusp region (almost immediately after

734 the arrival of the Alfvén wave down the field line from the magnetopause to the ionosphere).

735 However, flows over the polar cap (quantified by the transpolar voltage) evolve more slowly

736 and do not fully respond until 15-20 minutes later (*Lockwood and McWilliams,* 2021),

737 consistent with the Expanding-Contracting Polar Cap model (*Morley and Lockwood*, 2005) -

738 although we note that quasi instantaneous responses are also possible if the magnetosphere

739 has been pre-conditioned by prior magnetopause reconnection (*Morley and Lockwood*, 2005).

740 Hence determining the timescale that is relevant to a given response is a multi-faceted and

741 complex problem.

742 Figure 6 is the same as Figure 5, but for another value for d that has been proposed in the

743 literature, namely $d = 2$ (e.g., *Kan and Lee*, 1979; *Borovsky,* 2013. *Lyatsky et al.*, 2007). This

744 reveals the $sin^2(\theta/2)$ has very different behavior to $sin^4(\theta/2)$. At all τ, the distribution is

745 symmetric about 0.5 and the mean value (vertical dashed line) and the value for in-equatorial

746 field (vertical green line) are both always at 0.5. For τ up to about 15 min., this yields a

747 uniform distribution with $sin^2(\theta/2)$ with just small peaks at zero and unity that decay as τ is

748 increased. This even distribution makes $sin^2(\theta/2)$ an attractive choice if studying timescales

749 up to about 15 min. However, for $\tau = 1$ hr and above the distribution takes on some

750 undesirable characteristics, with most samples coming from near-in-equatorial field and fewer

751 from the extremes near 0 and 1. As discussed below this has some consequences

752 In the literature values for d between 1 (*Fedder et al.,* 1991, *Borovsky* 2008) and 6 (*Temerin*

753 *and Lee*, 2006; *Balikhin et al.*, 2010) have been proposed and used. From the above, the

754 choice of IMF orientation factor and of the averaging timescale both have a subtle effect on

755 the coupling function fitting by changing the weighting given to the data samples. The central

756 limit theorem means that the same effect applies to other factors in the coupling function, but

757 the effects are less marked because they do not start from as extreme a distribution for 1-min

758 values as does the IMF orientation factor. One key insight here is that we should not expect a

759 coupling function that works well at one timescale to be equally effective at another. Hence

760 some of the differences between the coupling functions proposed in Table 1 will have arisen

761 from the different averaging timescales used.

762 The behavior in Figures 5 and 6 is very different to that obtained by an average-then-combine

763 procedure given by equation (12) (not shown). In these cases, the distribution tends to

764 maintain its high-resolution form up to τ of about 1 day when it starts to narrow under the

765 central limit theorem. However, as τ is further increased it gets noisy and the broadens again

766 as the means of both the Y and Z components of the IMF tend to zero. The key point is that

767 this behavior is purely an artefact of the average-then-combine procedure, and the combine-

768 then average is what mimics the physics of the magnetosphere. The distributions of the other

769 parameters in the coupling function are largely log-normal and also influence the net

770 distribution of C_f, but it is the IMF orientation factor that has the most marked effect and the

771 imprint of its strange distributions is clearly seen in C_f (*Lockwood et al.,* 2019b; c).

3-ii. Optimum exponent *d* of the IMF orientation factor

772

773   In section 2 we defined the optimum lags for the interplanetary data, δt_p, and found that they

774   were not significantly influenced by the choice of the exponent *d* in the $sin^d(\theta/2)$ IMF

775   orientation factor. In this section, we define the optimum *d* using those lags. We vary *d* over

776   the full proposed range (we used values from 1 to 7.5 in steps of 0.01) and using the optimum

777   lags δt_p, we optimized *a*, *b* and *c* to maximize the correlation *r* at each *d*. The results are

778   shown for Figure 7, using the same format as Figure 3.

779   The top panel of Figure 7 shows that for Φ_P , *am* and *AL* , the correlation has a peak at quite

780   low *d*, specifically *d* = 2.1 for Φ_{PC} (in mauve) and *d* = 1.3 for *am* (in blue) whereas for *AL* (in

781   green) the peak correlation is at *d* = 3.7, very close to the value found by *MEA17*. The

782   bottom panel shows how the other exponents (*a*, *b* and *c*) depend slightly on *d*. Note that we

783   have also used the *MEA15* averaging methods to generate hourly coupling functions C_f,

784    $[C_f]_{1hr}$ using Equation (11) (not shown): as expected from Figure 1g, the correlations for

785    $[C_f]_{1hr}$ were systematically lower than for $[C'_f]_{1hr}$ by about 0.05.   For a few sample values of

786   *d* (specifically 2, 3, 4 and 6) we also repeated the computation using $<C_f>_{1hr}$ (Equation 10):

787   in each case, iteration took over a thousand times longer than the corresponding fit using

788    $[C'_f]_{1hr}$, but the results for *a*, *b*, *c* and *r* were all the same for $<C_f>_{1hr}$ and $[C'_f]_{1hr}$ to within the

789   estimated uncertainties. From Figure 7a, it appears that the $sin^2(\theta/2)$ IMF orientation factor

790   performs best for Φ_{PC} and that an even lower *d* is best for *am* because they yield higher

791   correlation coefficients.

792   However, as discussed in the previous section, some of this is the favorable distribution of

793   samples that averaging brings about and the subsequent weighting of IMF orientations in

794   deriving the correlation coefficient. This is demonstrated by Figure 8 for fits to the Φ_{PC} data.

795   Figures 8a and 8b show that for a *d* value that is too low or too high the relationship between

796   C_f and Φ_{PC} is not linear (with curvature in the opposite sense in the two cases). Figure 8c is

797   for the peak correlation (*d* = 2.2) and it can be seen that the variation is not linear, but *d* is

798   slightly too small, giving the same curvature as seen in Figure 8a. Figure 8d shows that it

799   requires a slightly larger *d* (= 2.5) to give a linear variation, even though the correlation is

800   slightly lower and the rms deviation is slightly larger than for *d* = 2.2 that yields peak

801   correlation. The reason lies in the effect of the distribution of C_f values on the fits. The

802   colour contours reflect the point made in relation to Figure 4, namely that higher d causes a

803   greater density of points at low C_f and so biases the fits to lower values of Φ_{PC} and hence

804   northward IMF. This can be seen by comparing the colour contours in the various parts of

805   Figure 8.

806   An interesting point to note is that the variation in Figure 8c could be interpreted as a

807   saturation effect at work, whereas it is in reality the application of a value of d that is too high.

808   Saturation is identified when the observed Φ_{PC} is not as high as we would expect for a given

809   coupling function for the prevailing interplanetary conditions (*Hairston et al.*, 2005;

810   *Shepherd*, 2007). Such an empirical identification and quantification of a saturation affect

811   assumes that the coupling function had been made to have a linear variation with Φ_{PC} and

812   Figure 8 demonstrates that deriving the coupling function using correlation coefficient can

813   give a non-linear variation of C_f with Φ_{PC}. It seems likely that saturation is a real

814   phenomenon – for example it is generated by MHD simulations *Kubota* (2017) and we note

815   that saturation the maximum $\Phi_{PC}/\langle\Phi_{PC}\rangle$ in Figure 8 is near 2.7 which corresponds to 100 kV

816   $(\langle\Phi_{PC}\rangle = 37$ kV) and saturation has generally been reported at larger Φ_{PC}, typically 150-200

817   kV and certainly at a level above 100 kV. In addition, the curvature caused by excessively

818   large d extends throughout all values of Φ_{PC} – unlike saturation effects. But we conclude

819   most of the data in Figure 8 are not influenced by saturation. Furthermore, the variation that

820   looks like saturation in Figure 8d is generated by an exceptionally large d (= 6.5) whereas the

821   effect of statistical weighting is to tend to underestimate d when using correlation. However,

822   we must remain aware that non-linearity introduced into the coupling function, caused by

823   statistical biasing towards certain IMF clock angles, can cause us to underestimate or

824   overestimate the true saturation effect.

825   There is second way to derive d that avoids the possibility of statistical bias, and this is

826   presented in the next section.

827   **3-ii. Test of the IMF orientation factor and linear regression coefficients**

828   *Vasyliunas et al*., (1982) provide a test for the optimum form of the IMF orientation factor

829   $F(\theta)$, such as $sin^d(\theta/2)$. This is based on the fact that we want the coupling function C_f to be

830   linearly related to the terrestrial response at all activity levels and not be biased in the way

831   illustrated by Figure 8. To evaluate this, we use the function G (i.e., C_f without the $F(\theta)$

832   factor, defined by Equation 14). We want C_f to vary linearly with the terrestrial index T

833   (which is either Φ_{PC} or am in the current paper). Hence we want

834      $T = s_T C_f + i_T = s_T GF(\theta) + i_T$ (16)

835   where s_T and i_T are the best-fit linear regression coefficients. This yields a requirement that

836      $F(\theta) = (1/s_T) \times (T - i_T)/G$ (17)

837   which we can test for. Equation (17) stresses the point that d is not an independent fit

838   variable from the other exponents because for a given a, b and c and set of interplanetary data,

839   G is proscribed which means there is a unique exponent d in $F(\theta) = sin^d(\theta/2)$ that ensures the

840   linearity of $C_f = G.F(\theta)$ with T. The supplementary material to *Lockwood et al* (2019b)

841   showed that this test yields $F(\theta) = sin^4(\theta/2)$ for a T of the SuperMAG *SML* index (equivalent

842   to *AL* but from a wider array of northern hemisphere stations) and a coupling function C_f of

843   P_α. We here repeat that test for Φ_{PC}, *am* and *AL* using our generalized form for C_f. Our

844   procedure takes each value of d in Figure 7 (which was varied between 1 and 7.5 in steps of

845   0.01) and the best-fit a, b and c for that d (which are given in Figure 7b) and compute G,

846      $F(\theta)$, and C_f and the linear regression coefficients between C_f and T, s_T and i_T. To test if the

847   linear equation (17) applies, we can divide the data up into equal-width averaging bins of

848      $F(\theta)$ for which we evaluate the means of both $F(\theta)$ and $(T-i_T)/G$. If the means for the bins of

849      $<(T-i_T)/G>$ are proportional to the means $<F(\theta)>$, then Equation (16) applies, and we know

850   that $F(\theta)$ is of the correct form for the proposed G to give a linear coupling function. Note

851   that averaging into bins of $F(\theta)$ removes the bias of the sample numbers towards low θ as the

852   means are not weighted by the number of samples that are in the bin. This is a particular

853   problem for higher values of d.

854   Figures 9, 10, and 11 give the results of this test of $F(\theta)$ for Φ_{PC}, *am*, and *AL*, respectively.

855   Parts (a), (b) and (c) of Figure 9 are examples of plots of $<(\Phi_{PC} - i_\Phi)/G>$ against $<F(\theta)>$

856 for $F(\theta) = sin^d(\theta/2)$ for three different values of d. Parts (a), (b) and (c) of Figures 10 and 11

857 are the corresponding plots of $<(am\text{-}i_{am})/G>$ and $<(AL\text{-}i_{AL})/G>$, respectively, as a function

858 of $<F(\theta)>$. In all cases we use the derived optimum G for the value of d in question (i.e.,

859 using the coefficients a, b and c given in Figure 7b). Averaging is carried out over 25 bins of

860 $F(\theta)$ of width 0.04, covering the full range of 0 to 1. Parts (a), (b) and (c) are, in all three

861 Figures, for d below, equal to and above the optimum value which is derived below: they

862 show that the best fit quadratic polynomial (the red line) and this is not linear in parts (a) or

863 (c) of the figures (the green line gives the best linear regression which will be the same as the

864 red line for a linear dependence). For the parts (a) of Figures 9, 10 and 11, the coefficient of

865 the power-2 term in the best fit quadratic polynomial is positive, whereas for the parts (c) it is

866 negative - i.e., the curvature of the best fit of the polynomial is in the opposite sense to in the

867 corresponding part (a). For the Parts (b) of all three figures, the fit is linear, and this is what

868 makes the d used in these cases the optimum value as it means the coupling function is

869 linearly related to the terrestrial index.

870 The derivation of the optimum value of d is shown in the Parts (d) of Figures 9-11 which plot

871 the power-2 term coefficient in the best fit-quadratic (a_Φ for Φ_{PC}, a_{am} for am and a_{AL} for AL)

872 as a function of the exponent d over the full range of values proposed in the literature. The

873 uncertainty band of this coefficient, at the 1-σ, 2-σ and 3-σ levels, are shown in shades of

874 gray in all three figures (but only easily discerned in Figure 10). The optimum d for Φ_{PC} , am

875 and AL are the values that make, a_Φ, a_{am} and a_{AL} (respectively) equal to zero – i.e., for which

876 the variation is linear. The 1-σ, 2-σ and 3-σ uncertainties in d are where the edges of the

877 uncertainty bands in a_Φ, a_{am} and a_{AL} fall to zero and this yields the vertical uncertainty bands

878 around the optimum d that are shown.

879 Figure 9 shows that the required d is 2.50±0.07 (at the 2-σ uncertainty level) for Φ_{PC}, Figure

880 10 shows that it is 3.00±0.22 for am and Figure 11 shows that it is 5.23±0.48. Hence the

881 optimum IMF orientation factors for Φ_{PC}, am and AL are not the same within 2-σ

882 uncertainties and in all three cases are larger than the value derived by correlation. Essentially

883 AL requires a function that is most like a half-wave rectified function and Φ_{PC} requires a

884 function that is least like one. The optimum d and their uncertainty bands for Φ_{PC}, am and AL

885 are also shown in Figure 7 which reveals that the uncertainties do not overlap even at the 3-σ

886   uncertainty level. Note that the commonly-used value of $d = 4$ is too large for Φ_{PC} and *am* but

887   too small for *AL*. Some agreement between the behavior of *am* and *AL* to be expected because

888   both are dominated, at high activity at least, by the effect of the substorm current wedge and

889   so do show considerable agreement (*Adebesin*, 2016; supplementary information to *Lockwood*

890   *et al.,* 2019a,). However, they are different indices and, as indicated by Figure 2, they have a

891   different relationship to the transpolar voltage. The values of s_T and i_T for the optimum d are

892   given in the Parts (b) of Figures 9-11.

893   The question then arises as to why the correlations r at these optimum d are slightly lower

894   than the peak correlations that are always found at slightly lower d, as can be seen in Figure

895   7a. The answer can be found by referring back to the analysis of the $d = 2$ case and the $F(\theta) =$

896    $sin^2(\theta/2)$ factor presented in Figure 5. This series of distributions shows that the dataset

897   becomes weighted towards the middle of the range of $sin^2(\theta/2)$ values as the timescale is

898   increased and there are fewer data constraining the large and low values. This is clearly

899   demonstrated by the distribution for these data with $\tau = 1$hr in Figure 5c. Hence although

900    $sin^2(\theta/2)$ gives very slightly higher r_p, it is only because the dataset becomes weighted

901   towards the center of the distribution with weaker weighting given to the extremes of low and

902   high $F(\theta)$. To test this conclusion, we carried out correlations where the data were divided

903   into 25 bins of $F(\theta)$ and for each bin, samples were selected at random such that all the $F(\theta)$

904   bins contained the same number of samples (the number that were in the least-populated bin),

905   thereby removing the sampling bias at the expense of losing data. The peak correlations were

906   indeed shifted to larger d and closely matched the values derived in Figure 7. These

907   correlation tests are still not bias-free because reducing the samples to the minimum number

908   is any one bin means that fits for some d have systematically higher sample numbers than

909   others. Nevertheless, this test is enough to confirm that the choice of d does influence the

910   correlation coefficients by preferentially weighting certain clock angles.

911   In contrast, in fitting the quadratic polynomial to the bins in parts (a), (b) and (c) of Figures

912   9-11, equal weight is given to the data points for the different $F(\theta)$ bins, despite the fact that

913   there are different numbers of samples in those bins. Hence, unlike the correlation coefficient

914   r, these fits are not influenced by the distribution of samples. Hence they provide a better test

915   of the optimum form of $F(\theta)$ that best describes the physics of solar-wind magnetosphere

916   coupling than do the correlation coefficients.

917   It can be seen from the bottom panel of Figure 7 that, in general, the uncertainty in d

918   introduces only small changes in the best-fit exponents a, b and c. However, the changes

919   across the uncertainty bands are not zero. Hence when we compute the uncertainties in a, b

920   and c we need to fold in both the fit uncertainties at the optimum d and effect of the

921   uncertainty in that optimum d.

922   With all 4 exponents and the linear regression coefficients now defined, the predicted

923   terrestrial index can then be determined from:

924    $$T_{pred} \;=\; s_T \, C_f + i_T \;=\; s_T \left\{ <B>^a <\rho_{sw}>^b <V_{sw}>^c <sin^d(\theta/2)> \right\} + i_T \qquad (18)$$

4. First-order check for overfitting

926   We here fit with three free fit parameters (a, b and c), we are pre-determining two others (d

927   and the optimum lag, δt_p) which can influence the results and hence, even for such a large

928   dataset, overfitting could be a problem. An initial test is to check that correlations are not

929   unrealistically high. We carried out tests for the effect of the noise introduced into our

930   correlations by the use of interplanetary data from spacecraft in a halo orbit around the L1

931   Lagrange point: the point being that the solar wind that is sampled by the spacecraft is not, in

932   general, the same as hits Earth because of spatial structure in the interplanetary medium. We

933   computed our generalized coupling function, covering the full range of a, b, c and d indicated

934   by Figure 7b, using data from both ACE, and THEMIS B for 2010-2019 (inclusive) when the

935   latter spacecraft was outside the bow shock in the near-Earth solar wind. For both craft

936   coupling several sample functions for $d = [2:1:6]$ were computed at one minute resolution and

937   then averaged with a 60-point running mean into hourly values with one minute cadence. The

938   optimum lag was determined as a function of time and the peak correlation evaluated from the

939   lag correlograms. The results did vary a little with the exponents used and, in particular,

940   correlations were lower for higher d, indicating IMF orientation structure was one of the

941   larger causes of noise. The 1-σ points of the overall distribution of correlation coefficients

942   were 0.83 and 0.91. Hence correlations above 0.9 are an immediate indication of potential

943   overfitting. Note also we have only considered one potential course of noise and we should

944 regard 0.9 as about the best correlation that we can achieve using upstream data from near the

945 L1 Lagrange point.

946 We here also test for overfitting in a straightforward way by dividing the data into just two

947 "folds" (whilst noting that machine-learning techniques often use several more folds for

948 different tasks) of roughly equal numbers of samples and then fitting to the one half and the

949 testing against the independent second half. Note also that testing also raises another set of

950 complications with a variety of performance metrics available for consideration (*Liemohn et*

951 *al.*, 2018), and the most appropriate one (or ones) for the application in question should be

952 deployed, especially in the context of forecasting (*Owens*, 2018).

953 We here use the optimum lags δt_p and d exponents derived above and consider only linear

954 correlation coefficient and root mean square (rms) error as test metrics.   The results are

955 demonstrated in Figures 12 and 13. The fit dataset used to define exponents *a*, *b, c* (for the

956 predetermined *d* for the parameter in question) was for 2012-2019, inclusive and the resulting

957 values are given in the legend to Figure 12. The same exponents and regression coefficients

958 were then applied to generate the predicted values for both the fit and the test subsets (1995-

959 2011) using Equation (18). Because there are so many datapoints, information is lost in a

960 scatter plot because so many points are overplotted: Figures 12 and 13 are therefore presented

961 as datapoint density plots. Comparing Figures 12 and 13 there are no obvious differences in

962 behavior, which is quantified by the correlation coefficients r and the rms deviations Δ

963 between observed and predicted values. For the predicted and observed Φ_PC, r is 0.853 and

964 0.886 for the fit and test sets, respectively, and Δ is 12.9 kV and 10.4 kV. Hence, by both

965 metrics, the test set is actually performing slightly better than the fit set.   For the predicted

966 and observed *am*, r is 0.813 and 0.822 for the fit and test sets, respectively, and Δ is 10.1 nT

967 and 10.7 nT. Hence in this case the correlation is very slightly better for the test set, but the

968 rms deviation is slightly better for the fit set. For the predicted and observed *AL*, r is 0.808

969 and 0.764 for the fit and test sets, respectively, and Δ is 84.4 nT and 83.8 nT. Hence in this

970 case the situation is the opposite to that for *am*, but differences are again very small.   In all

971 cases, the performance of the fits on the test set is essentially the same as for the fitting set

972 and there is no doubt that the coupling functions have predictive power.

973 Note from the plots presented in Figures 12 and 13 the influence that the *d* value has on where

974 data are in parameter space. For Φ_PC (which requires $d = 2.5$) there is a high density of

975　　samples over a large segment of the best-fit diagonal line. For *am* (which requires a higher $d =$

976　　3.0) the highest density of data is more closely confined to near the origin and this effect is

977　　even more marked for *AL* (which requires a yet higher $d = 5.23$). The key point is that the

978　　influence of northward IMF conditions on the derived general coupling function is greater for

979　　*AL* than it is for *am* and Φ_{PC} which needs to be remembered when we evaluate its

980　　performance.

981　　**5. Estimation of uncertainties and the influence of the number of samples**

982　　Figure 14 presents distributions of fitted values of the exponents *a*, *b* and *c* for three subsets of

983　　the transpolar voltage data and compares them to the value for the full set of $N = 65133$ samples

984　　(given by the vertical dashed line in each case). The distributions are generated by taking

985　　1000 random selections of *N* samples (from the total of $N_T = 65133$ samples with $n_e > n_{min} =$

986　　255 available): the values of *N* used were $N_T/25 = 2606$ (on average, corresponding to 1 yr of

987　　data); $N_T/10 = 6513$ (on average, corresponding to 2.5 yr of data) and $N_T/2.5 = 26503$ (on

988　　average, corresponding to 10 yr of data). The fraction of samples $n/\Sigma n$ are plotted in bins of

989　　width (1/30) of the maximum range of each exponent shown. In each case, three histograms

990　　are shown: the light grey histogram bounded by the mauve line is for $N_T/25$ samples, the

991　　darker grey bounded by the blue line is for $N_T/10$ and the darkest grey bounded by the black

992　　line is for $N_T/2.5$. The distributions are generally symmetric about the optimum value for the

993　　whole dataset, but not always so for the smallest *N* and, as expected, they narrow down

994　　toward the value for the full dataset as *N* is increased. The standard deviations of the

995　　distributions are given in each case on the plot. This analysis was repeated for the

996　　geomagnetic indices and the results were very similar (not shown). Distributions are broader

997　　and peaks lower for *am* and *AL* than for Φ_{PC}, which is expected because all plots presented

998　　thus far have had greater noise and larger uncertainties for the fits to the geomagnetic data.

999　　Figure 14 stresses how much in error an individual fitted value can be if smaller datasets are

1000　　used.   However, that both the mean and the mode of some of the distributions are shifted

1001　　from the value for the whole dataset when *N* is low, meaning that there are systematic errors

1002　　as well as random errors when sample numbers are low.

1003　　To determine the uncertainties in exponents *a*, *b* and *c* from our full dataset we assigned one

1004　　of the three exponents a fixed value that was then varied round its optimum value and the

1005 other two were fitted using the same Nelder-Mead simplex search procedure that was used to

1006 fit all three exponents in previous plots (again, we are using the optimum d and lag δt_p defined

1007 previously). The significances S of the difference between the correlation at a general value

1008 of the exponent and its peak value for the optimum exponent was then evaluated. As before,

1009 we evaluate $S = 1-p$ (where p is the probability of the null hypothesis that the correlations are

1010 the same) using the Meng-Z test and the 1-σ, 2-σ and 3-σ uncertainty level. This yields the

1011 uncertainty associated with the fit at the optimum d, which was added in quadrature with the

1012 uncertainty caused by the uncertainty range in that optimum d. The resulting 2-σ uncertainties

1013 are given with the optimum values in Table 2.

1014 **6. Significance of the differences between fits for transpolar voltage and geomagnetic**

1015 **activity**

1016 A notable feature established earlier is that the optimum d for Φ_{PC}, am and AL are not the

1017 same: the shaded areas of Figure 7 show that the uncertainties do not overlap for even the 3-σ

1018 level. Form Table 2 we can see that the exponents a, b, and c (of B , ρ_{SW}, and V_{SW}

1019 respectively) are also, in general, different. We conclude that there is no such thing as a

1020 universal coupling function and optimum coupling functions must be tailored to the index or

1021 indicator that they aim to predict. We have carried out a number of experiments of the kind

1022 illustrated in Figure 14 using randomly-sampled subsets of the data and found that some

1023 exponents that appeared to be the same, within predicted uncertainties, are found to be

1024 different, to very high significance, when we use the full dataset.

1025 7**. Discussion and Conclusions.**

1026 We have analyzed the optimum coupling functions for a dataset of 65133 hourly mean

1027 transpolar voltage estimates Φ_{PC} observed between 1995 and 2020 by the northern-

1028 hemisphere SuperDARN radar network and matching sets of fully-simultaneous am and AL

1029 index values, in the case of am these were linearly interpolated to the center times of the radar

1030 data hours from the 3-hourly index. We have fitted using a generalized mathematical function

1031 that encompasses many proposed coupling functions and have carried out only a 2-fold test

1032 for overfitting (i.e., dividing the data into a fitting and a test data set roughly equal sample

1033 sizes).

1034   Our aim in this paper has been to establish some important principles concerning how the data

1035   can be averaged and fitted to ensure the IMF orientation term used does not bias the data in a

1036   way that does not match the physics of solar wind-magnetosphere coupling and also to ensure

1037   that the coupling functions derived are linear predictors of Φ_{PC}, *am* and *AL*.

1038   Table 2 gives optimum values and the 2-σ uncertainties derived here. Also given is the

1039   correlation coefficient *r* obtained and the fraction of the variance explained, r^2. Note that

1040   correlations for *AL* and *am* here are for all the available data from 1995-2020 (but using the

1041   exponents derived here from the data subsets that are simultaneous with the radar data that

1042   meet the $n_e .> 255$ criterion (roughly a third of the full data). In addition, for *am* the raw 3-

1043   hourly data are used to evaluate *r* and r^2 rather than the interpolated hourly values. The

1044   correlations for Φ_{PC} are for only the $n_e > 255$ data. It should be remembered that the noise

1045   introduced by spatial structure in the solar wind, on its own, limits *r* to about 0.9 (r^2 to about

1046   0.81) and there are other noise sources (propagation lag uncertainty, instrumental errors in

1047   both the interplanetary data and the terrestrial disturbance indicator, seasonal and/or *UT*

1048   effects on terrestrial data, data gaps, effects of averaging, nonlinearity of response, dipole tilt

1049   effects). The values in Table 2 are slightly higher than previously proposed coupling

1050   functions, but the gains in r^2 are marginal. It appears that coupling functions are achieving

1051   correlations almost as high as is possible for interplanetary observations made at L1 and the

1052   terrestrial disturbance data that we have available.

1053   Table 2 also gives the performance of some theoretical coupling functions. For Φ_{PC} these are

1054   simple prediction based on interplanetary electric field given by Equation (8) and the

1055   *Borovsky and Birn* (2014) formulae for interplanetary Mach number $M_A < 6$ and $M_A > 6$. For

1056   *am* we use the best-fit version of the *Vasyluinas et al*. (1982) energy input formulation, P_α

1057   (with $d = 2$ and coupling exponent $\alpha = 0.34$) and for *AL* we shown the P_α formulation with

1058   best fit values of $d = 4$ and $\alpha = 0.26$.

1059   Our empirical fits exceed all these theoretical values, as indeed they should as they have three

1060   free fit variables. The results are quite similar in r^2 achieved to other empirical studies: for

1061   example *McPherron et al.* (2016) explained 43.7%, 61.2%, 65.6%, and 68.3% of the variance

1062   in the hourly *AL* index using, respectively, epsilon ε (*Perrault and Akasofu*, 1978), $V_{SW}B_s$, the

1063   universal coupling function (*Newell et al*., 2007) and the optimum coupling function that they

1064   had derived which was $B_\perp^{0.79} N_{SW}^{0.10} V_{SW}^{1.92} \sin^{3.67}(\theta/2)$ (i.e., $a = 0.79$, $b = 0.10$, $c = 1.92$ and

1065 $d = 3.67$). Unfortunately, *Newell et al.* (2007) did not test the 20 coupling functions they

1066   considered against the *am* index. The closest they used to *am* was the *kp* index for which the

1067   main coupling functions correlation gave $100r^2$ that ranged from 30% for ε to 58% for their

1068   universal coupling function. However, we note that there is a ±20% peak-to-peak "McIntosh"

1069   pattern in *am* caused by dipole tilt effects (*Lockwood et al.,* 2020a) which our optimum

1070   coupling function does not attempt to allow for with a dipole tilt term. This makes predicting

1071   66.3% of the variation in *am* without it very encouraging.

1072   The correlation for our transpolar voltage coupling function is $r = 0.865$ which means we are

1073   predicting $100r^2 = 75\%$ of the variation in Φ_{PC}. This is as high as has any that has been

1074   reported previously and is for a much larger dataset. An early study by *Wygant et al.* (1983)

1075   from a limited number of satellite passes explained 55% of the variation in Φ_{PC} with the

1076   coupling function $BV_{SW} \sin^4(\theta/2)$ (i.e., $a = 1$, $b = 0$, $c = 1$, $d = 4$). Applying this to our 25-year

1077   SuperDARN dataset of 65133 samples with $n_e > 255$, and using all best practice (i.e.,

1078   computing the coupling function at one-minute resolution, averaging and the determining

1079   optimum lag) we find the *Wygant et al.* (1983) formulation explains 66% on the variance.

1080   *Mori and Koustov* (2014) surveyed the effectiveness of different coupling functions in

1081   predicting a Φ_{PC} values from 1 year of SuperDARN radar data. They found percentages of the

1082   variance explained ranging from 13% for ε in equinox up to 61% (for $B_\perp^{1/2} V_{SW}^{1/2} \sin^2(\theta/2)$;

1083   i.e., $a = 0.5$, $b = 0$, $c = 0.5$ and $d = 2$), the latter is close to the optimum found here and testing

1084   against our data set we find it explains 73.5% of the variance in Φ_{PC}, only very slightly lower

1085   than the value for our fit.

1086   However, the benchmark test in transpolar voltage prediction is set by the coupling function

1087   of *Boyle et al.* (1977) who reported correlations of up to 0.87, explaining 75% of the variance

1088   of Φ_{PC}, from observations from a number of Low-Earth Orbit satellites over a three-year

1089   interval. The coupling function they derived was the addition of two terms: $10^{-4} V_{SW}^2 +$

1090 $11.7B\sin^3(\theta/2)$ (where V_{SW} is in kms^{-1} and B is in nT). A concern of any additive fit of this

1091   kind is that it may be open to overfitting and may not apply on all timescales. However, we

1092   can now check for overfitting by testing it against the fully-independent SuperDARN Φ_{PC}

1093   data used here. The correlation we obtain is $r = 0.830$, and so 68.8% of the variance in our

1094 Φ_{PC} data is explained. This is not quite as high as *Boyle et al.* (1977) reported for their fit

1095   dataset, nor quite as high as the correlation we have found here; however, neither is it that

1096   much lower. However, if we take the two terms in the Boyle function separately, we find the

1097   correlation with V_{sw}^2 is very low with $r = 0.2$ ($100r^2 = 4\%$) but that with $B\sin^3(\theta/2)$ is 0.831

1098   ($100r^2 = 69.0\%$), and actually very slightly better than for the combination of terms. Hence,

1099   the key part of the Boyle et al. function has exponent $a = 1$, $b = 0$, $c = 0$ and $d = 3$.

1100   We have studied the effect of different procedures in deriving the hourly means. In addition to

1101   the best practice combine-the average, $<C_f>_{1hr}$, we computed all proposed coupling function

1102 $[C_f]_{1hr}$ using the procedure of *MEA15* (with averaging of 1-minute values of θ and $B_\perp$) and

1103   also $[C_f^*]_{1hr}$ for which θ and $B_\perp$ are both computed using hourly means of the B_Y and B_Z IMF

1104   components. Using $[C_f]_{1hr}$ instead of $<C_f>_{1hr}$ typically lowers the variance explained by

1105   between 5% and 3%, whereas using $[C_f^*]_{1hr}$ instead of $<C_f>_{1hr}$ typically lowers it by about

1106   20%-40%. For the *Boyle et al.* (1977) parameter the behavior is strange in that for $[C_f]_{1hr}$ the

1107   value is reduced from 68.8% to 68.0% but using $[C_f^*]_{1hr}$ it plummets to 4%. The reason is

1108   the first term has become the larger of the two because the coefficients of the two additive

1109   terms are no longer appropriate. Hence the first term of the Boyle equation has actually

1110   lowered the variance explained slightly but also made it unstable to the precise

1111   implementation. This is a general risk with additive terms.

1112   **7-i. The IMF orientation factor**

1113   As shown in Table 1, exponents d of an IMF orientation factor $sin^d(\theta/2)$ of between 2 and 6

1114   have been suggested from empirical studies and simulations with numerical global MHD

1115   models have suggested d as low as 1.5 (*Hu et al.*, 2009) or even 1 (*Fedder et al.,* 1991;

1116   *Borovsky*, 2008). For both the transpolar voltage Φ_{PC} and the *am* geomagnetic index, we find

1117   that the IMF orientation factors in the coupling function for all suggested d between 1 and 6

1118   all perform reasonably well in terms of the correlation coefficient. We find that marginally

1119   higher correlations for hourly averages for the low d exponents, the best correlations being for

1120 Φ_{PC} at $d = 2.1$, for *am* at $d = 1.3$. However, we have shown that the distributions mean that

1121   these low d values are favoured mainly because they weight the statistics towards near $\theta =$

1122   90° and against data for strongly northward IMF (θ approaching 0) and strongly southward (θ

1123   approaching 180°). The latter bias is, of course, particularly undesirable because periods of

1124 large θ drive the strong space weather which is often what we want the coupling function to
1125 predict and quantify.

1126 As shown by Table 1 a great many studies have used $sin^d(\theta/2)$ with $d = 4$ and this exponent
1127 has also been found for energy transfer across the magnetopause in MHD simulations of
1128 global energy transfer across the magnetopause (e.g., *Laitinen et al.*, 2007). From the
1129 requirement of linearity across all clock angles we find the optimum exponents d are
1130 2.50±0.07 for Φ_{PC}, 3.00±0.22 for *am* and 5.23±0.48 for *AL*.

1131 **7-ii. Other coupling function exponents**

1132 The values of the other exponents a, b and c (of B, ρ_{SW}, and V_{SW} respectively) do, in general,
1133 depend on the exponent d used in $sin^d(\theta/2)$. Some empirical fit studies have derived values
1134 for d that are not within the optimum range derived here, and the concern is that the
1135 associated a, b or c have also been shifted from optimum values to compensate.

1136 Table 2 shows our best fit exponents for Φ_{PC} are somewhat different to the values of $a = 1$, b
1137 $= -0.167$, and $c = 0.667$ expected for the theoretical coupling function Φ_{SW} based on the
1138 interplanetary electric field (Equation 8) and the differences imply that the reconnection
1139 efficiency η has quite considerable dependencies on all three parameters. Specifically, from
1140 our results and Equation (8) η appears to vary as $B^{-0.358}$, $\rho_{SW}^{0.185}$ and $V_{SW}^{-0.117}$. Work is
1141 needed to see if these inferred external influences are consistent with the analysis of *Borovsky*
1142 *and Birn* (2014) who concluded that the reconnection voltage is not a function of the
1143 interplanetary electric field at all.

1144 One surprising value is the relatively large c (the exponent of V_{SW}) for the *am* geomagnetic
1145 index. Table 2 shows that the estimated power input into the magnetosphere P_α fitted to the
1146 *am* index (for the 3-hr timescale) gives $d = 2$ and a coupling exponent $\alpha = 0.34\pm0.04$. From
1147 equation (4) this predicts $a = 0.68\pm0.08$, $b = 0.32\pm0.04$ and $c = 1.65\pm0.08$. Table 2 shows that
1148 although the values of a and b close to those expected for P_α, c is much larger than predicted
1149 by P_α.

1150 From energy coupling into the magnetosphere from numerical MHD simulations *Wang et al.*
1151 (2014) derive $a = 0.86$, $b = 0.24$ and $c = 1.47$ (with a d of 2.7, similar to the 3.0 found here)

1152 which is extremely close to the above exponents for P_α with $\alpha = 0.44$ found by *Lockwood et*

1153 *al.* (2019a). Together with our results, this strongly suggest the *am* index has an additional

1154 dependence on $\rho_{SW}^{0.13}$ and $V_{SW}^{1.03}$ for a given power input into the magnetosphere. *Lockwood*

1155 *et al.* (2020b) find that 75% of the variation in *am* is explained by the estimated power input

1156 and that some of the remaining variance is associated with the solar wind dynamic pressure

1157 $P_{sw} = \rho_{SW}V_{SW}^2$ combined with the dipole tilt. They argue this is the effect of squeezing the

1158 near-Earth tail, an effect *Lockwood et al.* (2020b) show is found in both global MHD

1159 simulations and in the inference of an empirical model of the magnetopause location.

1160 On the other hand, our results for Φ_{PC} and *AL* show almost no dependence on ρ_{SW}. The *AL*

1161 result is particularly surprising as *AL* depends on the substorm current wedge which should

1162 also be influenced by the squeezing of the tail. Figure 11 of *Lockwood and MacWilliams*

1163 (2021) shows influence of P_{sw} (and hence ρ_{SW}) on Φ_{PC}, *am* and *AL*; it is complex and

1164 behavior depends on the IMF B_Z component, but it is stronger at all B_Z for *am*.

1165 Figure 15 is aimed at understanding the difference between the dependences of *am* and *AL* on

1166 the solar wind dynamic pressure P_{sw}. It shows the (normalized) ratios of the geomagnetic

1167 indices per transpolar voltage for (top panels) *am* and (bottom panels) *AL*, as a function of the

1168 normalized dynamic pressure P_{sw}. Figure 15 divides the data up into subsets for $\Phi_{PC} \leq 20$

1169 kV and $\Phi_{PC} > 20$ kV which roughly corresponds to northward and southward IMF, but more

1170 importantly is above and below the change of gradient in Figure 2b. For *am* there is an

1171 addition dependence of *am*, compared to Φ_{PC} that varies as P_{sw}^e where $e = 1$ for $\Phi_{PC} \leq 20$ kV

1172 and $e = 0.61$ for $\Phi_{PC} > 20$ kV (as shown by the dashed mauve lines). This is consistent with

1173 Figure 11 of *Lockwood and MacWilliams* (2021). On the other hand, for *AL* there is no

1174 additional dependence beyond that of Φ_{PC} ($e \approx 0$) for $\Phi_{PC} \leq 20$ kV and $e = 0.61$ for $\Phi_{PC} > 20$.

1175 Hence it is clear that *am* has a dependence on P_{sw} that is not present in Φ_{PC} and this is

1176 reflected in the coupling function we have derived for *am*. The reasons why the *AL* coupling

1177 function does not show the same P_{sw} effect are twofold. Firstly comparisons of Figures 15b

1178 and 15d, show that, for larger Φ_{PC}, the effect of P_{sw} on *AL* is weaker than that on *am*,

1179 However, more importantly, the coupling function for *AL*, with its larger *d* value, is weighted

1180 toward the behavior at $\Phi_{PC} \leq 20$ kV because of the weighting effect of large *d* and Figure 15c

1181 shows that *AL* has almost no dependence on P_{sw} at low Φ_{PC}. This strongly points to a major

1182 limitation of the standard coupling function formalism, namely they do not account for the
1183 interdependence of one factor on another.

1184 Comparing Figures 15b and 15d we can see that the effect of P_{sw} on *am* during southward
1185 IMF, and consequently enhanced Φ_{PC}, is greater than for *AL*. This implies range geomagnetic
1186 indices from mid-latitude stations, such as *am*, are responding to a factor that does not greatly
1187 influence *AL* in addition to the substorm current wedge (which dominates *AL*). *Matzka et al.*
1188 (2021) note that the k-index (range) variation at mid-latitude stations (and hence increases in
1189 *am* and *kp*) arises from large-scale ionosphere-magnetosphere current systems and they are
1190 sensitive to a much broader longitudinal sector of the auroral oval than is detected by auroral
1191 stations. Hence mid-latitude positive bays reflect larger scale currents as well as the more
1192 localized substorm current wedge (*McPherron and Chu*, 2017). Note that *Thomsen* (2004)
1193 attributes the proportionality of mid-latitude range indices and transpolar voltage to the effect
1194 of polar cap expansion and that is indeed a factor; however our results indicate that a parallel
1195 factor is that they are responding to the ionosphere-magnetosphere current circuits facilitated
1196 by the region 1 and region 2 field aligned currents and not just the substorm current wedge. It
1197 seems likely that this is the cause of the greater dependence of *am* of P_{sw} than *AL*.

1198 **7-iii. Universality of coupling functions**

1199 We have found that that although the coupling functions for Φ_{PC} and *am* could appear to have
1200 the same exponents if we use small datasets, when we use a very large one, as in this paper,
1201 the differences are shown to be highly significant and real. This implies that there is no such
1202 thing as a universal coupling function that can optimally predict both voltage disturbances in
1203 the magnetosphere and all geomagnetic disturbances and the coupling function needs to be
1204 tailored to the terrestrial disturbance indicator of interest in each case. This opens up new
1205 areas of systems analysis of the magnetosphere, namely combining the different responses of
1206 the various magnetospheric state indicators to different solar wind driving coupling functions
1207 (*Borovsky and Osmane*, 2019). It also has implications for how we might allow for
1208 "preconditioning" of the magnetosphere which is discussed in the next section.

7-iv. Preconditioning

One major limitation of all the coupling functions discussed in this paper is that they assume that the terrestrial space weather index predicted is determined by the prevailing near-Earth interplanetary conditions only (allowing for the required propagation lag). This means that any preconditioning of the magnetosphere-ionosphere system is neglected and will contribute to the noise in the fits. To start to make allowance for preconditioning we have to make a distinction between two types: (i) preconditioning caused by the Earth's dipole tilt; and (ii) preconditioning that depends on the prior history of the solar wind.

7-iv-i. Preconditioning by dipole tilt

Preconditioning by the dipole tilt can change the response of the magnetosphere, giving a larger or smaller response to a given solar wind forcing. This is an external factor depending on Earth's orbital characteristics which means it should be highly predictable. Studies show that genuinely global geomagnetic activity indices show a pronounced "equinoctial" (a.k.a. "Mcintosh") pattern with time-of-year and Universal Time, associated with the tilt of Earth's magnetic dipole axis (see reviews by *Lockwood et al*., 2020a; 2021). Attempts to expand the coupling function with a factor to allow for the effect of the dipole tilt were made by *Svalgaard* (1977), *Murayama et al*. (1980), and *Luo et al*. (2013) and dipole tilt effects have been included in the filters used in the linear prediction filter technique (*McPherron et al*., 2013).

However, the detail of how this should best be done does depends on the mechanism that is responsible and there are a large number of postulated mechanisms aimed at explaining the Mcintosh (a.k.a. equinoctial) pattern. One invokes the dipole tilt influence on ionospheric conductivities within the nightside auroral oval and postulates that the electrojet currents are weaker when conductivities caused by solar EUV radiation are low in midnight-sector auroral ovals of both hemispheres (*Lyatsky et al.,* 2001; *Newell et al.*, 2002). Other proposals invoke tilt influences on the dayside magnetopause reconnection voltage (*Crooker & Siscoe*, 1986; *Russell et al.,* 2003) or the effect of tilt on the proximity of the ring current and auroral electrojet (*Alexeev et al.,* 1996) or tilt effects on the stability of the cross-tail current sheet through its curvature (*Kivelson & Hughes*, 1990; *Danilov et al.*, 2013; *Kubyshkina et al*., 2015). All of these effects have the potential to reproduce the McIntosh dipole tilt pattern, but

1239   which if any, are effective remains a matter of debate. Recently, strong observational

1240   (*Lockwood et al.,* 2020b) and modelling (*Lockwood et al.,* 2020c) evidence argues that the

1241   amplitude of the McIntosh pattern increases with solar wind dynamic pressure, suggesting

1242   that the dipole tilt influences the degree of squeezing of the near-Earth tail by solar wind

1243   dynamic pressure. Given that dynamic pressure effects are included in most coupling

1244   functions via the ρ_{SW}, and V_{SW} terms, and that the effect is reasonably simultaneous with other

1245   solar wind effects, we might expect this effect to influence best-fit coupling exponents by

1246   raising b and c for geomagnetic activity but not for transpolar voltage. Thus, this mechanism

1247   has some relevance to understanding why the coupling function for transpolar voltage may be

1248   so different from that for the *am* index, as discussed in the previous section.

7-iv-ii. Preconditioning related to prior solar wind history

1250   The storage-release system manifest in substorms shows that the response of the

1251   magnetosphere is inherently non-linear: the effect of a given burst of southward-pointing

1252   IMF, for example, is different at the start of the growth phase (when the open magnetospheric

1253   flux is flow) compared to at the end of the growth phase (when it is high). Hence the response

1254   that depends on the state of the magnetosphere is in at the time, and that is set by the prior

1255   history of solar wind magnetosphere voltage coupling. One technique to allow for the non-

1256   linearity of response caused by this type of preconditioning is local linear prediction

1257   [*Vassiliadis et al*., 1995; *Vassiliadis, 2006*]. In this technique, moving average filters are

1258   continually calculated as the system evolves and these are used to compute the output of the

1259   system for this filter. The filter used is derived or selected according to the state of the system.

1260   Another way of dealing with this non-linearity is by using neural networks (e.g., *Gleisner and*

1261   *Lundstedt*, 1997). Our finding that the coupling function is significantly different for

1262   transpolar voltage and geomagnetic activity is significant in this respect. It means that if, for

1263   example, we wanted at allow for preconditioning due to the open flux in the magnetosphere,

1264   we would want to look at the prior history of an optimum coupling function for dayside

1265   reconnection voltage but would need to use a different coupling function to best predict, for

1266   example, the geomagnetic disturbance.

1267   A number of other physical mechanisms have been proposed as ways of further

1268   preconditioning the magnetosphere. They include: mass loading of the near-Earth tail with

1269   ionospheric O^+ ions from the cleft ion fountain (*Yu and Ridley*, 2013); the formation of thin

1270   tail current sheets (*Pulkkinen and Wiltberge*r, 2000); the development of a cold dense plasma

1271   sheet (*Lavraud et al*., 2006). Another proposed preconditioning effect is the effect on the

1272   reconnection rate in the cross-tail current sheet of enhanced ring current, as has been proposed

1273   by *Milan et al*. (2008; 2009) and *Milan* (2009). The magnetosphere sometimes responds to

1274   continued solar wind forcing (over a period of tens of minutes) by generating a substorm, or a

1275   string of substorms and sometimes with a steady convection event (e.g., *Kissinger et al*,

1276   2012). Studies (e.g., *Gleisner and Lundstedt*, 1999) have demonstrated that the response of

1277   the auroral electrojet indices depends on the current *Dst* value. *O'Brien et al.* (2002) studied

1278   two intervals in which the solar wind coupling function was similar, one of which resulted in

1279   an isolated substorm and the other in a steady convection event. They noted the main

1280   difference was the pre-existing state of the magnetosphere in that prior to the substorm, the

1281   magnetosphere was quiet but whereas before the steady convection event the magnetosphere

1282   was already undergoing enhanced activity. *McPherron et al.* (2005) estimate that about 80%

1283   of steady convection events are associated with a substorm onset but thereafter the

1284   magnetospheric behavior diverges. The work of *Juusola et al*. (2013) strongly suggests that

1285   enhanced ring current is the reason that a steady convection event forms as opposed to a

1286   substorm, quite possibly through the mechanism proposed by Milan and co-workers.

1287   Hence preconditioning of the magnetosphere undoubtedly occurs through at least one

1288   mechanism, and this will be an inherent noise factor in the derivation of a simple correlative

1289   coupling function and hence a major limitation on the performance of that coupling function.

1290   The problem is that not only are the effects of the various mechanisms on the response

1291   different, the time constants of the prior activity that is influencing the response will be

1292   different in each case. This means that the time profiling of any preconditioning

1293   quantification factor in a coupling function using the prior history of the interplanetary

1294   parameters will depend on the mechanism.

1295   To underline this point about the importance of the mechanism that is causing pre-

1296   conditioning, note that some mechanisms, such as the cold dense plasma sheet, would

1297   emphasize prior periods of quiet, northward IMF conditions as giving higher activity for a

1298   given input (*Borovsky & Denton*, 2006; 2010; *Lavraud et al.*, 2006), whereas others, such as

1299   the ring current enhancement mechanism would emphasize prior periods of enhanced solar

1300   wind magnetosphere coupling. The time constants for forcing in the build-up to ring current

1301   enhancements (*Lockwood et al.,* 2016) are different to those for the development of a cold,

1302   dense plasma sheet (*Fuselier et al.,* 2015). Yet another proposed preconditioning mechanism

1303   involves the effect of solar wind dynamic pressure and thus would introduce yet another

1304   different precursor time profile (*Xie et al*., (2008). Some of these preconditioning effects have

1305   been predicted by numerical modelling (e.g.. *Lyon et al*., 1998; *Wiltberger et al*., 2000) and it

1306   is quite possible that we may need numerical simulations to isolate the preconditioning effects

1307   and determine how best to allow for them.

1308   However, if we are to make these improvements to coupling functions to allow for

1309   preconditioning, we will need to remember that they will, inevitably, introduce more free fit

1310   parameters, making tests to guard against overfitting ever more important.

1690 **Table 1.** A list of proposed coupling functions that share the general functional form $B^{a} \rho_{SW}^{b}$
1691 $V_{SW}^{c} F(\theta)^{d}$ used here. The first column gives the basis of the formulation in each case, which
1692 is given in the second column. Columns 3-6 give the exponents a, b, c and d and column 7 the
1693 $F(\theta)$ function used (h.w.r. stands for "half-wave rectified"). Column 8 gives the time
1694 resolution of the data on which the function was mainly developed and used. The last column
1695 is a reference to a paper using or proposing the formulation. Note that in some cases the
1696 formulation is not proposed as a viable coupling function and has only used to make
1697 comparisons with proposed coupling functions, some are physical properties of the
1698 interplanetary medium and given here only to record the exponents a, b and c that they yield.

* for all 3-hourly data ** for interpolated 1 hourly data • for all 1-hourly data •• for simultaneous 1-hourly data

1699 **Table 2.** The best fit exponents a, b, c and d and the resulting peak correlation coefficient r_p
1700 for the terrestrial parameters Φ_{PC}, am and AL from fits using the data from the range of dates
1701 given. Uncertainties in a, b and c allow for both the fit uncertainties at a given d and the
1702 uncertainty caused by the uncertainty in d. The correlation coefficients are for all available
1703 data for 1995-2020: for Φ_{PC} this means the hourly 65,133 samples with the mean number of
1704 radar echoes exceeding 255; for am this means the 69,028 3-hourly means with simultaneous
1705 interplanetary data yielding a valid hourly coupling function; and for AL this means the
1706 241,848 hourly means with simultaneous interplanetary data yielding a valid hourly coupling
1707 function. The best-fit exponents are derived always from the 65,133 samples (using the
1708 optimum lag), using interpolated values in the case of am and simultaneous means for AL.
1709

Figure 1. Comparison of combine-then-average, average-then-combine and our compromise hybrid procedure for averaging 1-minute data into 1-hour data ($\tau = 1$hr). In all panels, the horizontal axis gives the result of the combine-then-average approach which is what we ideally would wish to use to mimic solar wind forcing of the magnetosphere. The vertical

1714   axes in (a)-(e) give the result of an average-then-combine procedure. In each case the fraction

1715   of samples $n/\Sigma n$ is color-coded, where n is the number of samples small bins. The raw data

1716   used are 9,930,183 valid 1-minute integrations of estimated power input to the

1717   magnetosphere, P_α , and 11,646,678 valid 1-minute values of the IMF clock angle θ and

1718   tangential component $B_\perp$ observed between 1995-2020 (inclusive). (a) is for the coupling

1719   function P_α for $\alpha = 1/3$ and $d = 4$ (the normalizing factor P_o is the arithmetic mean of P_α for

1720   all datapoints) in bins of P_α/P_o of size 0.08. The x axis shows the means of one-minute values

1721   of P_α , $< P_\alpha >_{1hr}$ and the y axis the values $[P_\alpha *]_{1hr}$ computed from 1-hour averages (including

1722   computation of the clock angle $[\theta]_{1hr}$ and the transverse magnetic field $[B_\perp]_{1hr}$ from hourly

1723   means of the IMF components $<B_Z >_{1hr}$ and $<B_Y>_{1hr}$). (b) is the corresponding plot for G,

1724   which is P_α without the IMF orientation factor; (c) is for the IMF clock angle (in the GSM

1725   frame of reference) θ in bins that are $2° \times 2°$; (d) is for the tangential IMF component $B_\perp =$

1726 $(B_y{}^2+B_x{}^2)^{1/2}$ in bins of 0.5nT $\times$ 0.5nT and (e) is for $sin^d(\theta/2)$ in bins 0.01×0.01. Part (f)

1727   compares $<B_\perp>^a$ with $<B_\perp{}^a>$ (where $a = 2\alpha$ for the P_α coupling function) and part (g)

1728   compares $<sin (\theta/2)>^d$ with $<sin^d(\theta/2)>$. In part (h) the y-axis is the result of our hybrid

1729   averaging procedure for P_α, $[P'_\alpha]_{1hr}$, defined by Equation (15).
Figure 2. Data density plots of normalized geomagnetic indices as a function of normalized transpolar voltage, $\Phi_{PC}/<\Phi_{PC}>$ (a) the *am* index and (b) the *AL* index. The fraction of samples (on a logarithmic scale) in bins that are 0.03 wide in the *x* dimension and 0.06 in the *y* dimension. The black points are means in bins of $\Phi_{PC}/<\Phi_{PC}>$ that are 0.1 wide and the black error bars are between the 1-σ points of the distribution of normalized geomagnetic index in the bin. The mauve line is a 3rd-order polynomial fit to the means.
1738

Figure 3. (Top) Lag correlograms (linear correlation coefficient, r, as a function lag, δt) of predicted variations using 61-point boxcar (running) means of the coupling function C_f from 1-minute interplanetary parameters with hourly observations of the transpolar voltage Φ_{PC} (in mauve), the interpolated *am* geomagnetic index (in blue) and hourly means of the *AL* index (in green). Note that unless otherwise stated, C_f in this and later figures refers to hourly means $[C'_f]_{1hr}$, derived from our hybrid formulation, Equation (15). The Φ_{PC}, *am* and *AL* data are all for the full 25-year dataset, but only for hours when the number of SuperDARN radar echoes n_e exceeds the threshold n_{min}. This yields $N = 65,133$ data points. The hourly *am* data are derived from the observed 3-hourly *am* values using PCHIP interpolation to the mid-points of the hourly integration periods for the radar data. The lag $\delta t = 0$ means that the radar data and the Omni interplanetary data are averaged over the same one-hour interval and positive δt corresponds to the interplanetary data leading the terrestrial data. The exponent d is assumed to be 3 but tests of values between 1 and 6 made negligible differences to the optimum values of δt, δt_p, derived. The dark gray, lighter gray, and lightest gray areas define, respectively, the 1-σ, 2-σ and 3-σ uncertainty bands in the lag δt_p and are defined using the Meng-Z test (see text for details). The vertical dashed lines give the lag δt_p that yields the peak r, r_p, which is 0.862 at $\delta t_p = 18.5 \pm 1.3$ min for Φ_{PC}, 0.818 at $\delta t_p = 31.5 \pm 4.0$ min for *am*, and 45.3±7.0 min for *AL*, the quoted uncertainties being at the 2-σ level. (Bottom) The best-fit exponents a, b and c as a function of δt (lines marked by squares, triangles and circles, respectively), derived using the Nelder-Mead search algorithm to maximise r.
1760

Figure 4. Distributions of 1-minute interplanetary parameters relating to IMF orientation in the GSM frame of reference: (a) the IMF B_Z component; (b) the IMF B_Y component; (c). the ratio $|B_Y|/B_Z$; (d). the clock angle $\theta = tan^{-1}(|B_Y|/B_Z)$; (e). $sin(\theta/2)$; (f). $sin^2(\theta/2)$; (g). $sin^4(\theta/2)$; and (h) $sin^6(\theta/2)$ in mauve, $U(\theta)cos(\theta)$ in blue (where $U(\theta) = 0$ for $\theta < 90°$ and $U(\theta) = -1$ for $\theta \geq 90°$) and $B_S/4.5$ in green (where B_S is the half-wave rectified southward component of the IMF, $B_S = -B_Z$ for $B_Z < 0$ and $B_S = 0$ for $B_Z \geq 0$: the factor 4.5 is used because it makes the mean value on the axis used the same as for $sin^6(\theta/2)$ and $U(\theta)cos(\theta)$ for the scale used). The data are 116,466,78 1-minute samples from the Omni database for 1995-2020 (inclusive), and the vertical axis is the fraction of samples in each bin, $n/\Sigma n$, where n is the number of samples in bins that are 1% in width of the range shown on the horizontal axis in each case. Vertical dashed lines give the mean value for the whole interval.
1772

Figure 5. Distributions of the IMF orientation factor $F(\theta) = sin^d(\theta/2)$ for $d = 4$, where θ is the IMF clock angle in GSM coordinates, for data averaging timescales τ of: (a) 1 minute; (b) 15 minutes; (c) 1 hour (used in this paper); (d) 2 hours; (e) 6 hours; (f) 1 day; (g) a solar rotation period of 27 days and (h). one year. The numbers of samples, n, as a fraction of the total number Σn, in bins 0.01 wide are shown in each case and the dataset used is the same as in Figure 4. The vertical mauve dashed lines are for the overall average of all samples. The vertical green line is at $\theta = 90°$ for which the IMF lies the GSM equatorial plane. Note that the lowest bin in $sin^4(\theta/2)$, which is 0-0.01, corresponds to a range in θ of 0-36.9° whereas the highest bin (0.99-1) corresponds to 171.9-180°.
1782

Figure 6. Distributions of the IMF orientation factor $F(\theta) = sin^d(\theta/2)$ for $d = 2$, in the same format as Figure 5 and for the same dataset. Here the lowest bin in $sin^2(\theta/2)$, which is 0-0.01, corresponds to a range in θ of 0-11.5°, whereas the highest bin (0.99-1) corresponds to 168.5-180°.
1787

Figure 7. Analysis of the effect of the exponent of the *d* of the $F(\theta) = sin^d(\theta/2)$ IMF orientation factor for all $N = 65133$ samples which meet the criterion of the hourly mean number of radar echoes $n_e > n_{min} = 255$. For each value of *d*, the value of the other three exponents *a*, *b*, and *c* are derived by the Nelder-Mead simplex search method to maximise the correlation coefficient *r* between the hourly lagged coupling function C_f. The results for observed Φ_{PC} are in mauve, interpolated hourly values of *am* are in blue and hourly means of *AL* in green. The vertical dashed lines mark the peak correlation in each case, the vertical solid lines the optimum *d* (that gives linearity and determined from Figures 9, 10 and 11) and the gray areas the 1-σ, 2-σ and 3-σ uncertainty bands of the optimum *d*. (a). The correlation coefficients, *r*, as a function of *d*. (b). The best fit values of the exponents *a* (identified by squares), *b* (triangles) and *c* (circles) as a function of *d*.
1799

Figure 8. Data density plots of normalised coupling function $C_f / \langle C_f \rangle$ as a function of normalised transpolar voltage in the same format as Figure 2 (except mean values and the 1-σ ranges are shown in red and the colour scale is linear in fraction of samples, rather than logarithmic). The black dashed line in each panel is the best linear regression to the individual data pairs and the green dashed line is the best second-order polynomial fit. The panels are for (a) $d = 1.1$; (b) $d = 2.2$; ; (c) $d = 6.5$ and (d) $d = 2.5$. In each panel, the best-fit exponents a, b and c are given for the d used (as in Figure 7), as is the correlation coefficient, r and the root mean square (rms) deviation of the normalised C_f and Φ_{PC} value pairs, Δ_{rms}.
Figure 9. Tests of the IMF orientation term, $F(\theta) = sin^d(\theta/2)$ for the transpolar voltage Φ_{PC}. Parts (a), (b) and (c) show plots of the means of $R_\Phi = (\Phi_{PC} - i_\Phi)/G$ as a function of mean $F(\theta)$, both averaged for 25 bins of $F(\theta)$ that are 0.04 wide. G is given by Equation (14), where C_f is the optimum coupling function for the optimum exponents a, b and c for the d in question, as shown in Figure 7. (a) is for $d = 1.5$, (b) for the derived best d of 2.50 and (c) is for $d = 5$. The green and red lines are linear and quadratic fits, respectively, to the mean values. The values of the linear regression coefficients s_Φ and i_Φ (see equations 16 and 17) are given in (b), where the s_Φ values are for $B_\perp$ in nT, N_{SW} in 10^6 m^{-3}, V_{SW} in km s^{-1} and m_{SW} in kg. (d). The mauve line is coefficient of the quadratic term of the second-order polynomial fit to the means, a_Φ, as a function of d: the optimum d gives a proportional relationship between $<R_\Phi>$ and $<F(\theta)>$, i.e., when $a_\Phi = 0$, marked by the vertical dashed line. Under the mauve line in three shades of gray area are the 1-σ, 2-σ and 3-σ uncertainty band in a_Φ, the limits to which define the corresponding uncertainty bands in the optimum d, giving a 2-σ uncertainty in the optimum d of ±0.07. Note that in this case for Φ_{PC} the differences between the uncertainty bands are often so small that they cannot be discerned; they are more clearly seen in Figure 10 for am. Part (b) confirms this proportional relation at this optimum $d = 2.50$ for which the exponents are given in Table 2.
Figure 10. The same as Figure 9 for the *am* index. The blue line in part (d) is the best-fit a_{am} under which the three gray areas define the 1-σ, 2-σ and 3-σ uncertainty bands in a_{am}, the limits to which define the vertical uncertainty bands in the optimum *d* shown. The optimum *d* giving the proportional relationship is $d = 3.00 \pm 0.22$ for which the exponents *a*, *b* and *c* are given in Table 2.
**Figure 11**. The same as Figures 9 and 10 for the *am* index. The green line in part (d) is the best-fit a_{AL} under which the three gray areas define the 1-σ, 2-σ and 3-σ uncertainty bands in a_{AL}, the limits to which define the vertical uncertainty bands in the optimum *d* shown. The optimum *d* giving the proportional relationship is $d = 5.23 \pm 0.38$ for which the exponents *a*, *b* and *c* are given in Table 2.
Figure 12. Datapoint density plots of predicted against observed values of (a) the transpolar voltage Φ_{PC}, (b) the *am* geomagnetic index, and (c) the *AL* index – each for their optimum d value defined in section 3. These data are for the fit dataset which is for 2012-2020. . In both cases, the optimum fit of C_f has been scaled to the data by ordinary least-squares linear regression. The numbers samples n (as a faction of the total number Σn) in bins, which are 1kV $\times$ 1kV wide in (a), 1nT $\times$ 1nT wide in (b), and 5nT $\times$ 5nT wide in (c), are colour-coded on the logarithmic scales given. The diagonal mauve lines mark perfect agreement of observed and predicted values. The correlation coefficient r and the root mean square deviation Δ of observed and predicted values are given in each panel, along with the total number of valid data-point pairs, N. The best fit exponents for Φ_{PC} are $a = 0.655$, $b = 0.052$, and $c = 0.668$ and the regression coefficients are $s_\Phi = 8.408$ and $i_\Phi = 13.45$ kV; for *am* they are $a = 0.847$, $b = 0.305$, and $c = 2.420$, with $s_{am} = 249.52$ and $i_{am} = 6.75$nT, for *AL* they are $a = 0.712$, $b = 0.052$, and $c = 1.709$ with $s_{AL} = 0.0759$ and $i_{AL} = 15.67$ nT. The regression slopes are for units of kV for Φ_{PC} and nT for *am* and *AL* and for the coupling function C_f computed using $B_\perp$ in nT, N_{SW} in $10^6 m^{-3}$, V_{SW} in km s^{-1}, and m_{SW} in kg.
1854

Figure 13. Same as Figure 12 but for the independent test dataset from 1995-2011, computed using the best-fit exponents, regression coefficients and optimum lags derived as used for the fit dataset (2012-2020). The correlation coefficients *r* and the root mean square deviations *Δ* are very similar to the corresponding values for the fit dataset shown in Figure 12. For these plots the data had no role at all in deriving the fit exponents and coefficients.
Figure 14. Distributions of fitted values of exponents a (left panel), b (middle panel) and c (right panel) for fits to the transpolar voltage, Φ_{PC}, drawn from the entire 25-year dataset of 65133 values with $n_e > n_{min} = 255$. The fraction of samples $n/\Sigma n$ in bins of width (1/30) of the maximum range of each exponent are plotted. In each case, three histograms are shown: (1) the light grey histogram bounded by the mauve line is for (1/25) of the whole dataset ($N = 2606$ samples, on average corresponding to 1 yr of data); (2) the darker grey bounded by the blue line is for (1/10) of the whole dataset ($N = 6513$ samples, on average corresponding to 2.5 yr of data); the darkest grey bounded by the black line is for (1/2.5) of the whole dataset ($N = 26503$ samples, on average corresponding to 10 yr of data). The standard deviation of the distribution is given in each case with the generic name σ_{xi} where x is the exponent in question and i is the number of the dataset number. The distributions are generated by taking 1000 random selections of N samples from the total of 65130 samples with $n_e > n_{min} = 255$ available. The vertical dashed lines give the values for the full set of 65130 samples.
Figure 15. Data density plots for (top) the normalized *am* index per unit transpolar voltage, $(am/\langle am\rangle) / (\Phi_{PC}/\langle\Phi_{PC}\rangle)$ and (bottom) the normalized *AL* index per unit transpolar voltage, $(AL/\langle AL\rangle) / (\Phi_{PC}/\langle\Phi_{PC}\rangle)$ both as a function of normalized solar wind dynamic pressure $(P_{SW}/\langle P_{SW}\rangle)$ and in the same format as Figure 2. The data are divided into two subsets by transpolar voltage with $\Phi_{PC} \leq 20$ kV in the the left-hand panels and $\Phi_{PC} > 20$ kV in the right-hand panels. The mauve lines are the variations of $P_{SW}^e/\langle P_{SW}^e\rangle)$ for best-fit exponents *e* of 1, 0.61, 0.01 and 0.25 in parts (a)-(d).
