**Key Points:**

- Urbanization correlates with the presence of shallow cumulus clouds.

- Urban clouds are driven by the enhanced sensible heat and dynamic drag imparted by the urban landscape.

- Urbanization cloud enhancement emerges as a crucial pathway responsible for reducing the afternoon Heat Index values.

18    **Abstract**

19    The study and simulation of the Urban Heat Island (UHI) and Heat Index (HI) effects in the

20    Houston-Galveston metropolitan area demand special attention, particularly in considering moist

21    processes aloft. During the warm season, the afternoon sea breeze phenomenon in this coastal

22    city acts as a natural air conditioner for city residents, facilitating the dispersion of moisture,

23    heat, and pollutants. To delve into the intricate relationships among urbanization, clouds, and

24    land-sea interactions, we conducted cloud- and urban-resolving simulations at a 900 m grid

25    resolution.  Results show that urbanization correlates with the presence of shallow cumulus

26    clouds, higher cloud bases, and increased cloud duration over the Galveston-Houston region

27    compared to rural areas. These urban clouds benefit from the enhanced sensible heat and

28    dynamic drag imparted by the urban landscape, thereby intensifying vertical mixing and

29    moisture flux convergence.  This dynamic interplay uplifts heat and moisture convergence,

30    contributing to the enhancement of moist static energy that sustains the additional urban

31    convection. Interestingly, our findings suggest that urbanization augments the mean HI while

32    mitigating its afternoon high. An urban circulation dome emerges, overpowering the influence of

33    land-sea circulations. Contrary to expectations, urbanization doesn't seem to promote a stronger

34    sea breeze that would favor moist and cooler air mass advection to the city. Instead, the influence

35    of urbanization on cloud enhancement emerges as a crucial pathway responsible for reducing the

36    afternoon HI values. Moreover, uncertainties in SSTs are closely linked to the sensitivities of

37    land-sea circulations, which in turn modulate UHI and extreme heat indicators.

38    **Plain Language**

39    Urbanization influences the meteorology by creating a warmer environment that enhances

40    excessive heat during the summer. Additionally, the warmer environment and the urban

41    buildings increase friction, leading to more mixing and in turn favoring the development of low-

42    level clouds.  We developed computer simulations aiming to understand these processes and

43    their interaction with the sea-breeze in this coastal city, and we found that these clouds help

44    ameliorate the excessive heat during the afternoon.

45

46    Keywords: Urban clouds, Urban Heat Island, Urban Circulation, Sea Breeze, Heat Index.

## 1   Introduction

48   This study is motivated by the need to characterize and better simulate excessive heat in

49   urban environments.  Increasing population in urban areas make cities more vulnerable to

50   extreme weather events, climate variations and warming trends.  It is likely that some of these

51   changes will be outside of the range of historical extremes (Simolo et al. 2011; Trenberth et al.

52   2015) and are expected to cause changes not only in mean, but also in extreme weather episodes

53   (USGCRP, 2018).  While there is relatively high confidence in the direction of changes in

54   extreme temperature episodes, decision-makers require more quantitative and detail information

55   to make better and more concrete adaptation plans to improve resilience in natural resources

56   management (Rosenzweig et al. 2014) and health related risks (Guo et al. 2018; Ebi et al. 2021).

57   The exposure of cities to extreme heat appears to be more critical under climate change scenarios

58   and is exacerbated by the high solar absorption of the urban environments (i.e., the Urban Heat

59   Island effect, hereafter UHI) (Fischer and Schär 2010; Schubert et al. 2012).  Hence,

60   understanding the processes modulating the extreme temperature is a necessary step to develop

61   reliable adaptation and mitigations strategies aiming to make cities more resilient (Cady et al.

62   2020; Zonato et al. 2021; Resilient Houston 2020; Houston Climate Action Plan 2020).

63   Recent studies have found that the urban environments not only modulate the temperature

64   via the UHI effect, but also clouds and precipitation (Loughner et al. 2011; Theeuwes et al. 2019;

65   Fan et al. 2020; Doan et al. 2023; Vo et al. 2023; Statkewicz and Rappenglueck 2023).  During the

66   daytime, observations (Theeuwes et al. 2019), long-term satellite clouds retrievals (Vo et al.

67   2023) and numerical simulations (Loughner et al. 2011; Fan et al. 2020; Theeuwes et al. 2021)

68   have shown that the urban environment enhance warm non-precipitating clouds (i.e., low-level

69   shallow cumulus clouds) and even extreme precipitation (Fan et al. 2020; Doan et al. 2023).

70    During the night, however, Vo et al. (2023) suggested that clouds can block outgoing longwave

71    radiation and exacerbate the UHI by suppressing the nighttime cooling.

72          The role of the urban environment on simulated warm non-precipitating low-level clouds

73    needs a more systematic and deeper assessment as it can be influenced by the geography and

74    climate of the region (Theeuwes et al. 2021; Vo et al. 2023; Chiu et al. 2022). For example, Vo

75    et al. (2023) observed that urbanization in cities near the Gulf Coast tend to show larger cloud

76    enhancements during the summer, compared to other regions in the continental United States.

77    For a single storm event, Fan et al. (2020) simulated the individual and combined effects of the

78    urban land-use/land-cover and aerosols on convective clouds, storm evolution and intensity.  In

79    agreement with Theeuwes et al. (2019, 2021), Fan et al. (2020) showed that Houston urban area

80    is related to earlier occurring and more persistent clouds due to a stronger urban heating.  They

81    also showed that the aerosol-cloud interaction effect can develop deeper convective mixed-phase

82    clouds and more intense storms as compared to the effect of the urban land-use/land-cover alone.

83          These cloud and precipitation enhancement favored by urbanization can modulate the

84    UHI and extreme heat indicators. It is possible that the enhanced daytime clouds serve as a self-

85    cooling mechanism by blocking the incoming solar radiation and increasing evaporative cooling.

86    In coastal cities, however, isolating the effect of urbanization is challenging because the land-

87    ocean sea breeze circulations can also invigorate clouds and precipitation (Loughner et al. 2011;

88    Zhong et al. 2017) and overwhelm the signals related to urbanization, and other important

89    processes such as aerosol-cloud interactions (Fan et al. 2020).  During the extreme warm season,

90    on the other hand, the relatively cold and moist air masses advected by the afternoon sea-breeze

91    phenomenon provide a natural air conditioning to the city's residents, and facilitates the

92    redistribution of pollutants, moisture, and heat.

93  The intricate interplay between Houston-Galveston urban morphology, local circulations,

94 and climate patterns significantly influences the formation and behavior of clouds over the city,

95 while their interactions with urban heat remain poorly understood.  This study aims at

96 investigating the phenomenon of urban-induced clouds in the Houston region, elucidating the

97 underlying mechanisms driving their formation, encompassing both cloud dynamics and

98 thermodynamics mechanisms, and exploring their intricate relationship with surface temperature

99 and urban heat.  To achieve this objective, we conducted urban-resolving and cloud-resolving

100 simulations (900 m grid size) using the Weather and Research Forecasting model (WRF; Powers

101 et al. 2017).  Incorporating a multilayer Urban Canopy Model focused over the Houston-

102 Galveston area, our simulations leverage state-of-the-art representations of urban morphology

103 and Local Climate Zones (Demuzere et al. 2022).  In Section 2, we describe the model

104 configuration, outline the observational data used for model evaluation, and elucidate the

105 rationale behind our experimental design, which aims to isolate the impacts of urbanization and

106 coastal influences.  Moving forward to Section 3, we present the evaluation results of our model,

107 and examine the model representation of the UHI intensity, heat index, and shallow cumulus

108 clouds. Furthermore, we delve into the analysis of pertinent dynamical and thermodynamical

109 processes within the mixed layer, as well as the intricate land-sea interactions that drive cloud

110 enhancement.  Finally, Section 5 offers a comprehensive discussion, reconciling new findings

111 and drawing conclusive insights from our study.

## 2  Data and Methodology

### 2.1  The Regional Climate Model Coupled with the Urban Canopy Model

We used the Weather Research and Forecasting model (WRFv4.3.2; Powers et al. 2017) configured to perform urban- and cloud-resolving simulations. For this, we implemented the urban canopy model (UCM) based on the multi-layer building effect parameterization (BEP) scheme, coupled with the Building Energy Model (BEM; Salamanca et al. 2010). This UCM option considers three-dimensional mass and momentum mixing and heat transfer between buildings and the atmosphere, providing a realistic and accurate representation of near-surface energy fluxes and air temperature in mid-latitude cities (Cady et al. 2020; Jin et al. 2021). We would like to stress that this is not an instance of model calibration, but an attempt to assess and understand the UCM's capabilities and related uncertainties. We used this UCM option, among others available, because it incorporates 11 Local Climate Zones (LCZ), with 10 built up categories that provide a better representation of the heterogeneity of urban areas as compared to the three built-up categories in other databases and UCMs.

In this study, we used a three nested domain configuration (8100 m, 2700 m, and 900 m) centered in Houston, with 61 vertical levels up to 100 hPa. To allow the innermost model domain to relax towards the scenario settings, we designed the borders to be at least 80 km away from the suburban areas of Houston. Our initial modeling tests showed significant numerical diffusion noise, highlighted as non-physical wind street patterns and thermal fields in the mixing layer with a spatial scale of two times the grid size. This problem is relatively common in high-resolution simulations during weak wind conditions and weak or unstable stratification (Knievel et al. 2007; Crosman et al. 2012). To overcome this issue, we imposed a spatial filter based on an explicit 6th-order numerical diffusion scheme with a non-dimensional rate of 0.12. Despite the potential over

135  smoothing in space of surface processes, the explicit diffusion treatment notably improved

136  simulations, and results were resistant and unsensitive to its implementation. Additionally, we

137  combined our experience and literature reports to determine other configurations and the selection

138  of physical parameterizations implemented in our model. We acknowledge that it is difficult to

139  find a model configuration that is superior under different flow regimes and for the large variety

140  of geography and urbanization settings. For parameterization of moist processes, we used the

141  Thompson double-moment microphysics, whereas convection and clouds parameterization are

142  resolved explicitly in all our model domains, except for the coarser grid (8100 m) where we used

143  the Kain–Fritsch scheme. Additionally, we used the Dudhia and Rapid Radiative Transfer Model

144  (RRTM) as shortwave and longwave radiation schemes, respectively; Noah-

145  Multiparameterization, Monin-Obukhov and Yonsei University (YSU) were selected for land-

146  surface model, surface layer, and planetary boundary layer (PBL) schemes, respectively. YSU

147  PBL scheme was used for its simplicity, low computational cost and recognized good performance

148  (Hendricks et al. 2020). The first 6 hours of the simulations were not considered to allow for the

149  model spin up. We used the GDAS/FNL (the Global Data Administration System/Final) re-

150  analysis dataset (National Centers for Environmental Prediction et al., 2015; hereafter "FNL") as

151  initial and boundary conditions data, with SST skin temperature updated as bottom boundary

152  condition SSTs every 6 hours.

153  ## 2.2  Land Use/Land Cover and Urban Characterization

154  An important consideration in urban canopy modeling is the characterization of the Land

155  Use/Land Cover (LULC) and urban categories. Most LULC products rely on remote sensing

156  surveys with urban classification that are either outdated, such as the National Urban Database

157  and Portal Tool (NUDAPT; Ching et al. 2009), or lack details even in major urban composition

158  features, such as the World Urban Database and Access Portal Tools version 2 (WUDAPT;

159  Brousse et al. 2016; Ching et al. 2018; Demuzere et al. 2021, 2022a). Additionally, differences

160  in the algorithms used to characterize urban categories and different data sources may result in

161  different urban coverage. We opted to implement the 100 m global map of LCZ (Demuzere et al.

162  2022) for the following considerations: it follows the WUDAPT protocol; it is based on more

163  modern (2016-2018) data than NUDAPT (2006), thus it captures a more recent snapshot of the

164  urban growth and with a better spatial resolution; and their land cover classification adapted to

165  the LCZ and WUDAPT that facilitate their implementation of the UCM BEM+BEP for 11

166  different urban categories, contrasting only three urban categories in the NUDAPT data.

167  Recently, the global LCZ map was introduced into WRF preprocessing system (Demuzere et al.,

168  2023). However, we did not implement this version as the LCZ rely on urban pixels from other

169  databases (MODIS and Copernicus), producing a smaller urban area in comparison to the

170  original global LCZ map for the study region. The preprocessing for WRF was performed using

171  the WUDAPT-to-WRF (W2W) python tool (Demuzere et al., 2022b).
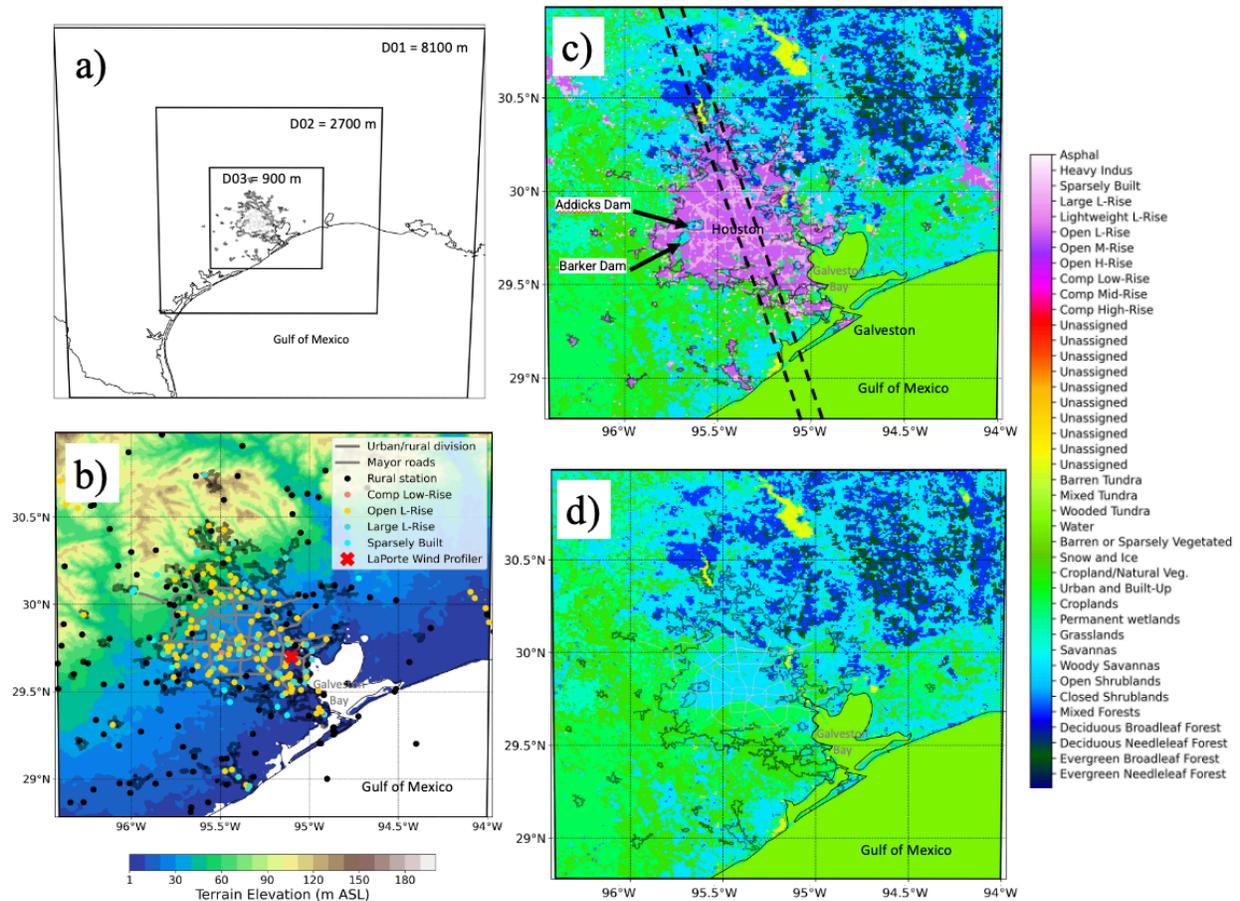

**Figure 1.** (a) WRF model nested domains (8000, 2700, 900 m grid sizes) and (b-d) details of the innermost model domain: (b) terrain elevation and the location of the NOAA LaPorte wind profiler site and the surface stations used in the model evaluation (from various sources), categorized by urban Local Climate Zones (LCZ; color coded symbols; 151 sites) or rural land cover (black symbols; 91 sites); (c) Land Use/Land Cover (LULC; contours) based on Demuzere et al. (2022) using LCZ categories for the urban areas and MODIS for rural areas; and (d) LULC after removing the urban areas and replacing them with the surrounding predominant rural vegetation. Dark grey contours indicate urbanization boundaries as of 2010 (Houston-Galveston Area Council, H-GAC; https://www.h-gac.com/Home) and light grey polygons show location of major intraurban roads. Dash lines in (c) show the location of the cross-city transect shown in the analysis.

## 2.3 Model Experiment Design

All simulations cover a 15-day period, between August 1 and 16, 2020, which was the warmest period of 2020, and normally the warmest period of the year (Palecki et al. 2021). We excluded the initial 6 hours due to model spin-up issues. During the simulation period, however, different meteorological regimes could have modulated sea-breeze related convection

187    invigoration: a pre-trough regime (1-3 August), followed by a post-trough regime (4-5 August),

188    and then the Bermuda high anticyclone was more pronounced (5-16 August) (Wang et al. 2022;

189    https://earth.nullschool.net/).  To isolate the effect of these intermittent and scattered summer

190    showers (mostly concentrated during August 1-3), we constrained our analyses to times without

191    significant observed precipitation events (< 5 mm) in the Houston-Galveston area.

192    **2.3.1   SST Sensitivity**

193          The city's proximity to the Gulf of Mexico and the complex coastal shape of Galveston

194    Bay warrants a careful look at the SST data used by the model as bottom boundary conditions

195    (Hawbecker and Knievel 2022).  When comparing the default FNL SST fields used by the model

196    against measurements from remotely sensed NOAA-SNPP VIIRS SST (available daily at 4 km

197    grid size; several snapshots per day; Bouali and Ignatov 2014) and buoy datasets

198    (https://www.ndbc.noaa.gov/), we found an average offshore cold bias of nearly -1 °C (SFig. 1).

199    To improve the SST fields, we implemented a time-space Barnes interpolation approach with

200    successive correction using a Gaussian weight function departing from the untreated FNL SSTs

201    until optimizing the agreement between the interpolated function and the measurements (the

202    unbiased SSTs; SFig. 1).

203    **2.3.2   Clouds, Urbanization and Weather Sensitivity**

204          We conducted a series of simulations to elucidate the intricate interplay between

205    synoptic, sea-breeze, and cloud effects alongside urbanization's influence on meteorology.

206          Firstly, we established a Baseline simulation incorporating the LCZ categories to mimic

207    the urban landscape, using the unbiased SST as bottom boundary conditions (as outlined in

208    Section 2.3.1), along with cloud and precipitation physics representations (microphysics and

209    convection). Clouds and showers, partly driven by the afternoon sea-breeze, can significantly

210    impact the UHI effect (Morris et al., 2001). However, given the relatively short duration of our

211    simulations (15 days) and the sporadic nature of moist processes aloft, we executed a clear sky

212    simulation (hereafter referred to as 'Clear sky') by deactivating microphysics and convection in

213    the model. This method assists in partially isolating the impact of clouds and showers on the

214    Urban Heat Island (UHI) effect. However, fully disentangling the role of clouds in the UHI

215    presents a challenge due to their potential influence on mesoscale circulations, such as sea

216    breezes and urban-rural thermal-related flows, which are known to also affect the UHI

217    phenomenon.

218        To assess uncertainties associated with SSTs, we performed a simulation utilizing the

219    original (untreated or biased) FNL SSTs fields (hereafter referred to as 'Biased SSTs').

220    Additionally, we isolated the urbanization effects within mesoscale circulations by eliminating

221    all urban areas from the domains (hereafter referred to as 'No City'), replacing all urban grid

222    points with representative regional vegetation (Fig. 1d). A summary of the simulations conducted

223    in this study, along with their respective descriptions and justifications, is provided in Table 1.

224    Of note is that all references to the model simulation pertain to the Baseline scenario, unless

225    explicitly stated otherwise.

226    **Table 1.** Description of model scenarios simulated in for this study.

| Scenario name | Description | Justification |
|---|---|---|
| *Baseline* | *All sky simulation including cloud and convective processes (moist processes) and bias correction of offshore SSTs (unbiased SSTs). Includes WUDAPT data.* | *Full physics simulation using outlined parameterizations and state-of-the-art LULC categories from LCZ. Systematic biases associated with offshore SSTs are removed.* |
| *Clear Sky* | *Same as Baseline but without clouds and moist convective processes.* | *Isolate the role of clouds and precipitation relative to Baseline.* |
| *Biased SST* | *Same as Baseline but using the untreated biased SSTs* | *Assess the sensitivity of Baseline to SST perturbations or refinements (e.g., bias corrections).* |
| *No City* | *Same as Baseline but replacing the urban LCZ categories with rural land cover* | *Isolate the role of the urbanization in the meteorology.* |

## 2.4 Surface Station and Upper-Air Winds

227

228     We utilized all available, quality-controlled surface station monitoring sites in the

229     Houston area and surrounding rural regions. Data was retrieved using the Synoptic Data

230     Application Programming Interface (API) using data from the National Weather Service, Remote

231     Automated Weather Station, and Texas Commission on Environmental Quality (TCEQ)

232     Continuous Ambient Monitoring Station (CAMS) network. After stringent quality

233     assurance/quality control checks (e.g., removing outliers, visual inspection, addressing atypical

234     diurnal cycles of temperature and relative humidity), a total of 208 stations were deemed reliable,

235     with 151 situated in urban settings (110 in Open L-Rise, 12 Sparsely built, 28 in Large L-Rise,

236     and 1 in Open H-Rise) and 91 in rural areas (Fig. 1b).  It is acknowledged that certain

237     uncertainties may exist due to urban network siting and sensor variability, some of which were

238     mainly designed for air quality monitoring purposes (e.g., TCEQ sites).

239     These surface station observations significantly contributed to assessing the model

240     confidence in representing the diurnal temperature, relative humidity, and wind behavior, while

241     facilitating the analysis of derived parameters such as minimum temperature (Tmin), maximum

242     temperature (Tmax), Urban Heat Island (UHI) effect (calculated as the difference between

243     representative urban and rural sites), and Heat Index, based on the Rothfusz (1990) formulation

244     utilizing temperature and relative humidity data.  Model confidence was assessed through

245     metrics including model bias, root-mean-square-error (RMSE), and Pearson correlation

246     coefficient.  In order to enable a comprehensive comparison between urban and rural sites, we

247     employed a bootstrapping methodology with replacement. This approach was designed to assess

248     the uncertainty surrounding the impact of proximity to the coast and the consequent land-sea

249     interaction effects. The bootstrapped analysis included an almost equal distribution of stations

250    between coastal and inland locations relative to downtown Houston, situated approximately 75

251    km from the Gulf coast. Consequently, coastal sites were classified as being within a coastal area

252    if their distance from the Gulf coast was less than 75 km, while inland sites were those located

253    further away.

254          To assess the accuracy of simulated low-level winds, we compared them against

255    observations from the Cooperative Agency Profilers wind profiler at La Porte (LPTTX), situated

256    near the coast along the northern shores of Galveston Bay (Fig. 1b).

## 3   Results

### 3.1   Model Evaluation

259          Figure 2 shows the observed and simulated diurnal patterns of surface temperature,

260    relative humidity, Heat Index, and zonal and meridional winds, corresponding to urban and rural

261    sites in the domain.  In general, the model adequately follows the diurnal median patterns for the

262    evaluated parameters, but several biases are apparent, with the model showing a systematic low

263    relative humidity bias (also exhibited in the water vapor mixing ratio, not shown) that is more

264    intense during the afternoon and nighttime. The model surface temperature shows an in-phase

265    diurnal evolution with a warm bias in the late afternoon and during the nighttime. Of note is that

266    model nighttime temperature biases are even warmer in urban sites compared to rural sites.  The

267    amplitude of the diurnal cycle of the simulated HI exhibits a smaller magnitude compared to

268    observational estimates, characterized by a warm bias during nighttime and a cold bias during

269    daytime periods. These biases in HI stem from a concurrent warm bias in surface temperature

270    during the day and a dry bias in relative humidity during the night.  Notably, these HI biases are

271    more pronounced over urban sites, where the dry bias is more discernable.

272        Fig. 2 shows that the diurnal distribution of the simulated zonal winds closely follows the

273    observations, with shifting from relatively calm southeasterlies in the morning to stronger

274    southwesterlies in the afternoon and nighttime. Part of the wind shifting feature is typically a

275    result from the planetary boundary layer diurnal inertial oscillation (Blackadar 1957); albeit

276    diurnal variability at this region can also be driven by the land-sea circulation. A striking surface

277    circulation feature is that wind speeds are stronger over rural areas compared to urban areas (Fig.

278    2).  This urban-rural wind speed differences are overemphasized by the model: the simulated

279    winds show a slightly stronger southerly wind bias in urban sites, whereas it almost doubles the

280    observed southerly wind in rural sites.

281        To further assess low-level wind patterns (< 3 km), data from the La Porte wind profiler

282    (Fig. 3) were incorporated into our evaluation analysis. Both model simulations and

283    observational data revealed a nocturnal wind acceleration, a phenomenon associated with the

284    prevailing summertime Great Plains low-level Jet circulation, which extends towards the Gulf

285    coast in eastern Texas (Pu and Dickinson, 2014). However, notable disparities emerged between

286    the model and the observed conditions at La Porte. The model exhibited a more pronounced and

287    enduring nocturnal maximum, suggesting a deeper intensity compared to the observed jet. This

288    finding agrees with the results of Ngan et al. (2013), who identified analogous biases in model-

289    generated low-level wind patterns and intensities across various land surface and planetary

290    boundary layer (PBL) parameterizations.  Although it is out of the scope of this study, an energy

291    and momentum budget can help elucidate and shed more light on the origin of the existing

292    stronger southerly low-level wind biases.

           Urban stations (151)                                Rural stations (91)
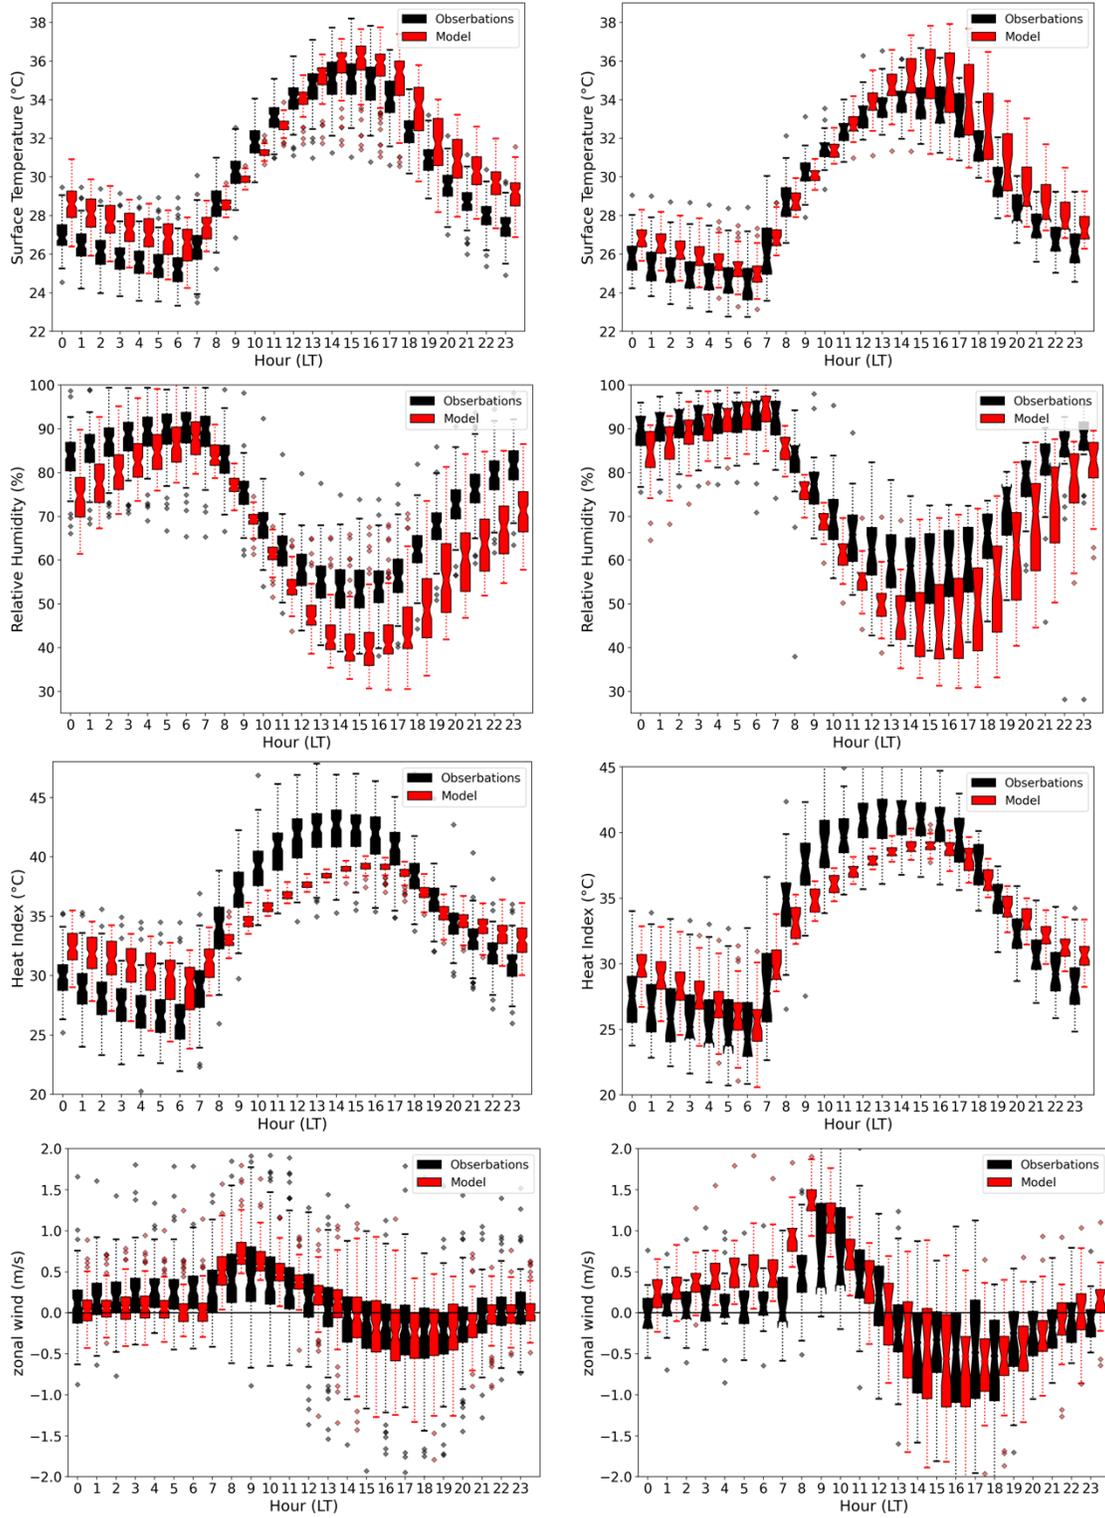

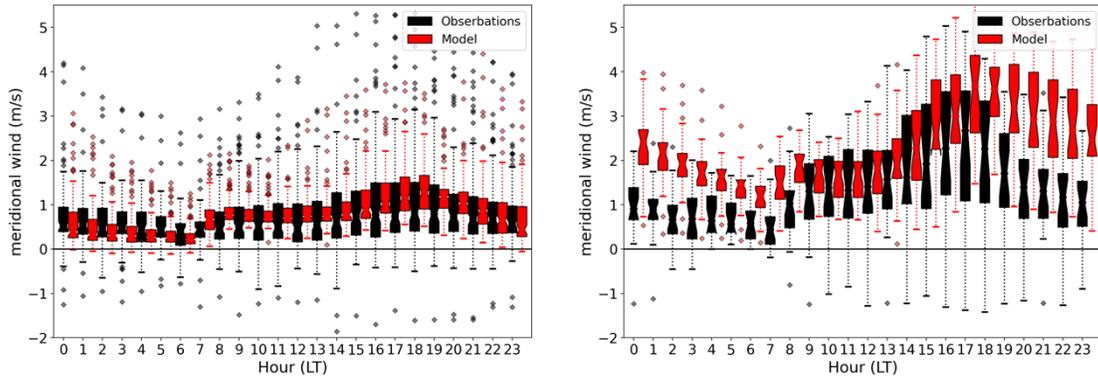

**Figure 2.** Baseline model and observed diurnal cycle distribution of (top to bottom panels) surface temperature, relative humidity, and zonal and meriodonal wind components for stations in the Houston urban (151 sites; left panels) and rural regions (91 sites; righ panels).

**Figure 3.** Low-level-diurnal mean horizontal wind speed (contours) and wind vectors (with the north direction pointing upwards) for (a) La Porte Wind profiler observations, (b) Baseline model winds, (c) Baseline minus observations differences and (d) Baseline minus No City differences.

Figure 4 shows the model scenarios biases (Table 1) for surface temperature and relative humidity, evaluated at all available surface station sites (see SFig. 2 for evaluation of the RMSE

302   and Pearson correlation coefficients). In general, model errors are small and well within the

303   model typical behavior in perturbed sensitivity experiments (Ancell et al. 2018; Wang et al.

304   2023), but some systematic error signals emerged as a function of the scenario simulations and

305   by compositing rural and urban areas.  The Baseline simulation shows a systematic warm bias

306   for Tmin and Tmax. Not surprisingly, over the urban areas the No City scenario shows a

307   relatively colder bias when compared to all the urbanized scenarios.

308        The role of clouds in the model performance is apparent. Notably, the Clear sky scenario

309   has warmer and drier biases during the daytime, as the lack of clouds increases the incoming

310   solar radiation, balanced by more sensible and ground heating.  At night, the warmer biases of

311   the Clear sky scenario, as compared to Baseline biases, suggest that the outflux ground heating

312   dominate the faster longwave radiation cooling (Fig. 5).

313   When comparing the Baseline to the Biased SSTs scenario, refining the offshore SSTs towards a

314   warmer SSTs have an inland warming effect, with larger differences during early morning.

315   Therein, a surprising result is that bias differences between Baseline and Biased SSTs are smaller

316   during the daytime than during the early morning. This is related to the direct sea-breeze

317   advection of warmer maritime surface temperature that does not develop a significant sensitivity

318   in Tmax in comparison to Tmin.  Therefore, the model biases highlight that the surface

319   temperature sensitivity between the Baseline and Clear sky simulations (-0.56 °C difference) are

320   significantly larger than that between the Baseline and Biased simulations (0.25 °C difference;

321   see also SFig. 2). By construction, the bias trends of the scenarios in this model evaluation

322   procedure are somehow expected, but some potential non-linear impacts related to changes in

323   cloudiness and circulation, which motivate the main objective of this study, are not as apparent.

324

a) Surface temperature bias
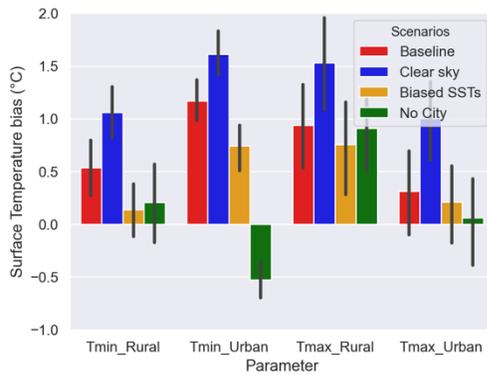

b) Relative humidity bias

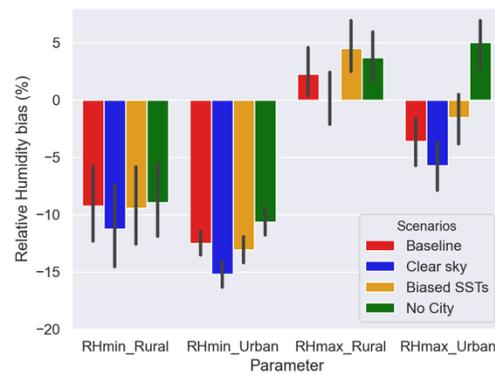

**Figure 4.** Model biases for each scenario (Table 1) evaluated at surface station sites for minimum and maximum (a) surface temperature and (b) relative humidity. Surface station sites are categorized as Urban or Rural according to land use/land cover types. Analysis is constrained to non-rainy periods as described in Section 2.

## 3.2 Urban Heat Island

Table 2 compares surface station observations and corresponding simulations composited as a function of the rural and urban categories. The UHI was estimated as the difference between the mean temperature of the stations in the urban and rural sites, determined for Tmax and Tmin. Since the distance from the coast (i.e., from the station to the nearest simulated ocean grid point) can have an impact in the UHI estimates (not shown), we used the median of the distance from the coast to subsample and balance the number of sites located near the coast with those far from the coast. Observations show a more pronounced UHI effect for Tmax (afternoon) than for Tmin (early morning). When contrasting the model at sites with surface station data, the Baseline model is overemphasizing the Tmin UHI effect and underemphasizing that of Tmax. Table 2 also shows that the Baseline simulation is related to a stronger Tmin and a milder Tmax UHI than the Clear sky scenario. This is not surprising due to the role of clouds in the long- and short-wave radiative balance (Brenguier et al. 2000). Biased SST simulation yields a similar and a more intense early morning and afternoon UHI, respectively. Finally, the relatively small

343    temperature differences in the No City simulation show that the composited UHI in the other

344    simulations are linked to urbanization.

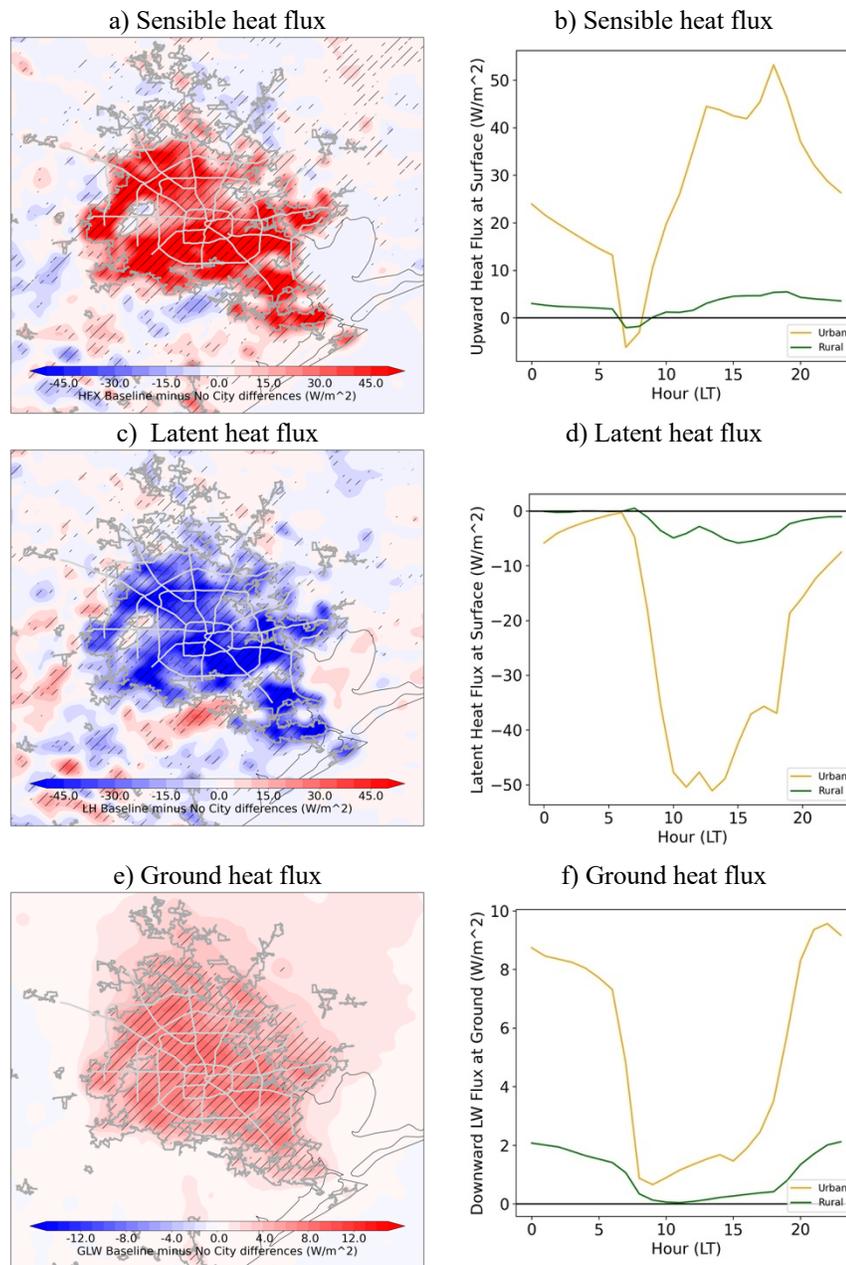

**Figure 5.** Mean Baseline minus No City differences for (a) sensible, (c) latent, (e) ground heat fluxes. Hatched areas indicate that differences are significant with a 95% confidence level. Dark grey contours indicate urbanization boundaries as of 2010 (Houston-Galveston Area Council, H-GAC; https://www.h-gac.com/Home) and light grey show location of major intraurban highways. Spatially averaged diurnal (b) sensible, (d) latent and (f) ground heat fluxes for Baseline minus No City differences composited by urban and rural areas.

350    Another method to reveal the intensity of the UHI is by comparing the Baseline and the

351    No City scenarios.  Fig. 6 shows the spatial patterns of the UHI effect for Tmin and Tmax,

352    estimated as the Baseline minus the No City simulated differences. The nighttime and daytime

353    UHI differences are striking, highlighting a very pronounced and significant early morning UHI

354    effect and a less intense afternoon UHI effect (Fig. 6c). The urbanization intensity and intra-

355    urban vegetation islands are related to some of the cool UHI patches within the city (Fig. 1c).

356    Notably, the Baseline minus the No City differences remain significant downwind and to the

357    north and northwest of the city boundary (Fig. 6).  Since some stations are located downwind of

358    Houston, this advection of UHI can reduce the actual UHI intensity estimates shown in Table 2.

359    Hence, the overemphasis of the early morning (Tmin) UHI can be partly attributed to the

360    overestimation of surface temperature in the urban areas.

361    **Table 2.**  Observed and simulated (mean and bootstrapped 95% confidence interval using for 100 iterations with
362    replacement) Tmin and Tmax at surface station locations composited by urban (117 sites) rural (91 sites) sites (see
363    Fig. 1). The UHI effect is estimated as the urban minus rural difference for observations and each scenario, with
364    bold estimates highlighting significant UHI effect with p-value of 0.05 and lower.

| | Tmin [°C] | | | | Tmax [°C] | | | | Tmin [°C] | | Tmax [°C] | |

365

## 3.3   The Role of Shallow Cumulus Clouds

367    Figures 7a and 7b show the mean vertical maximum cloud mixing ratio for the Baseline

368    and No City scenarios, respectively. The Baseline urbanized area exhibits thicker and more

369    abundant clouds compared to the "urban area" in the No City scenario, primarily attributed to

370    afternoon shallow cumulus clouds (Fig. 7c). In contrast, the No City scenario shows a lower

371    cloud cover with less apparent differences across the domain. The impact of urbanization on the

372    cloud patterns is complex and can vary temporally and spatially.  It is important to note that the

373    patchy cloud structures are a result of the relatively short simulation, limiting a point-by-point

374 comparison between these scenarios. However, extending the model integration over a longer

375 duration is expected to reveal more robust and discernable differences. For instance, the cloud

376 frequency climatology by Wilson and Jetz (2016) unambiguously demonstrates that

377 urbanization-related clouds are more frequent than clouds in the surrounding rural areas. This

378 cloud climatology, developed at a 1 km grid size, further reveals intraurban variability in cloud

379 frequency, dependent on urbanization intensity and urban green infrastructures, as observed in

380 the less cloudy areas over the vegetated Addicks and Barker flood control reservoirs in the west

381 of Houston (Fig. 1c).

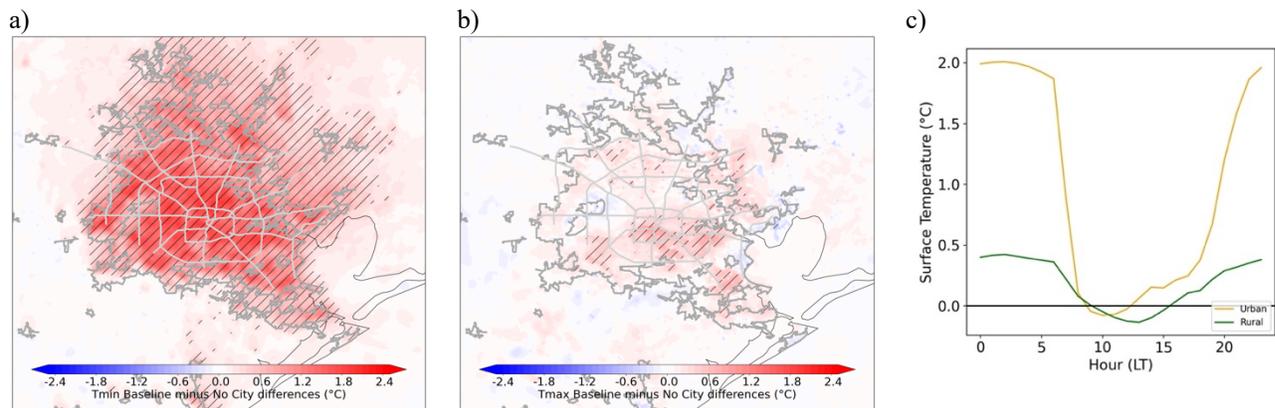

382 **Figure 6.** Mean Baseline minus No City differences for (a) Tmin and (b) Tmax. Hatched areas in (a) and (b)

383 indicate that differences are significant with a 95% confidence level. Dark grey contours indicate urbanization

384 boundaries as of 2010 (Houston-Galveston Area Council, H-GAC; https://www.h-gac.com/Home) and light grey

385 show location of major intraurban highways. (c) Spatially averaged diurnal surface temperature for Baseline minus

386 No City differences composited by urban and rural areas.

387 The impact of urbanization in the clouds is more apparent by averaging their properties in

388 space. Fig 8 presents the spatially averaged diurnal-pressure cloud mixing ratio for both the

389 Baseline and the No City scenarios, only considering urban grid points. In general, inland

390 shallow cumulus clouds begin forming early during the daytime, growing deeper and more

391 abundant around 15 LT. The Baseline simulation shows that these clouds are more abundant in

392 the urban areas than in the rural areas, while Baseline minus No City differences further confirm

393 that over built-up land cover these shallow cumuli are more abundant, grow deeper and last

394 longer than over vegetation. Although smaller differences are observed when comparing clouds

395 between the Baseline and No City scenarios in rural areas (not shown), some cloud mixing ratio

396    differences are simulated, likely due to the advection of UHI effects downstream into rural

397    regions (as shown for temperature in Fig. 6).

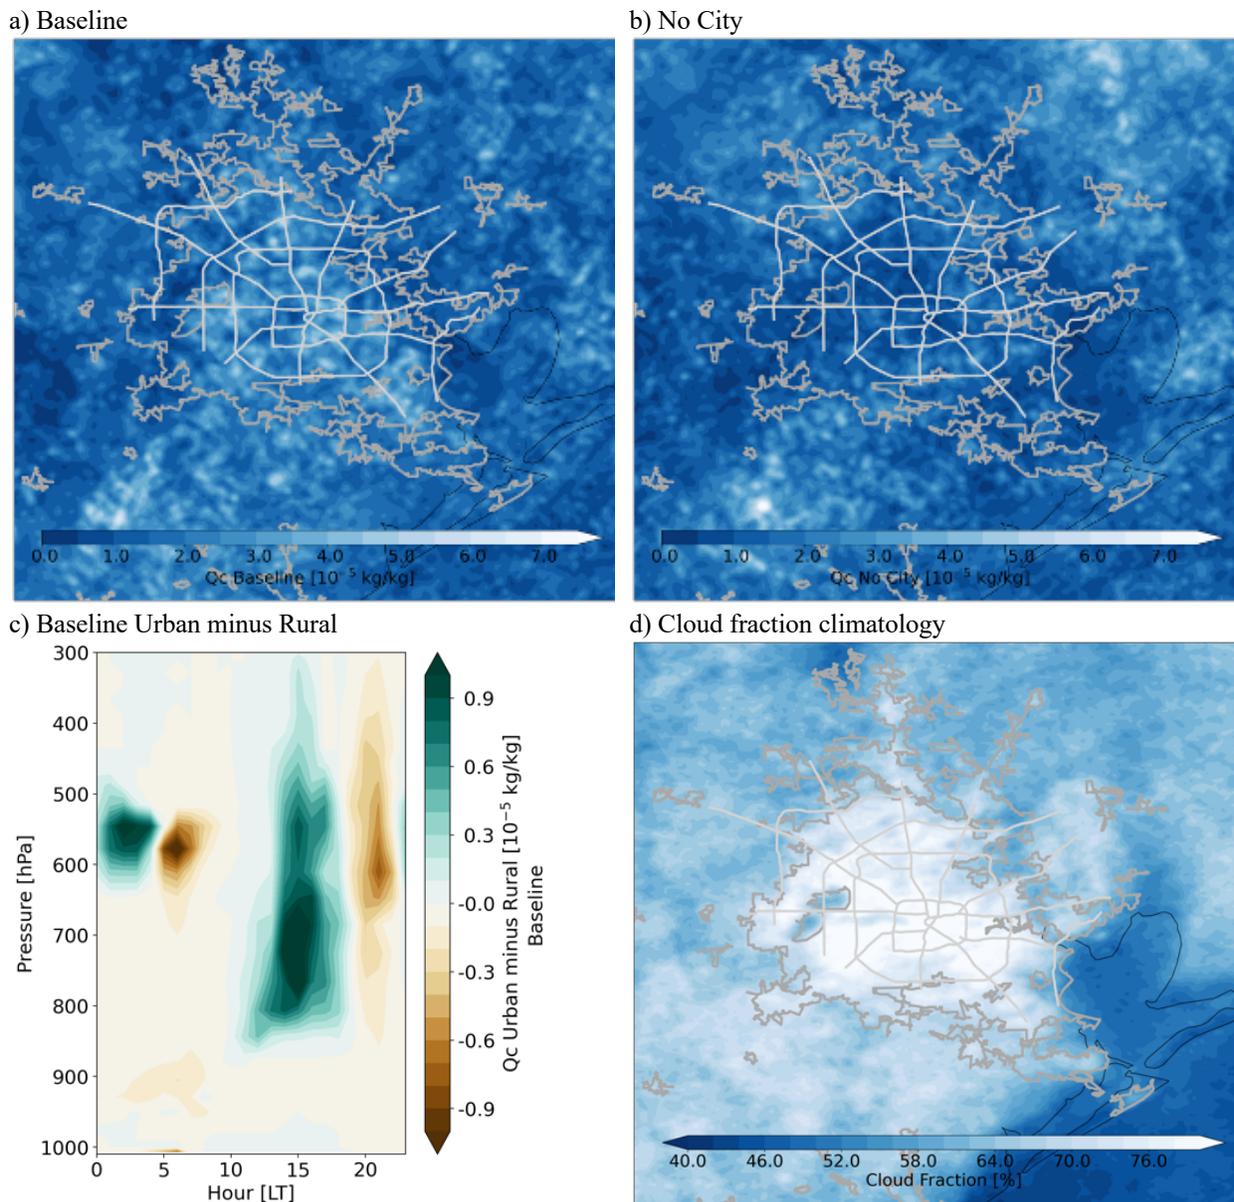

398    **Figure 7.** Mean vertical maximum cloud mixing ratio for (a) Baseline and (b) No City scenarios, and (c) Baseline

399    diurnal-pressure urban minus rural composites. (d) Cloud fraction climatology based on 15 years of twice-daily

400    Moderate Resolution Imaging Spectroradiometer (MODIS) satellite images (source Wilson and Jetz 2016). Dark

401    grey contours indicate urbanization boundaries as of 2010 (Houston-Galveston Area Council, H-GAC;

402    https://www.h-gac.com/Home) and light grey show location of major intraurban highways.

403

404
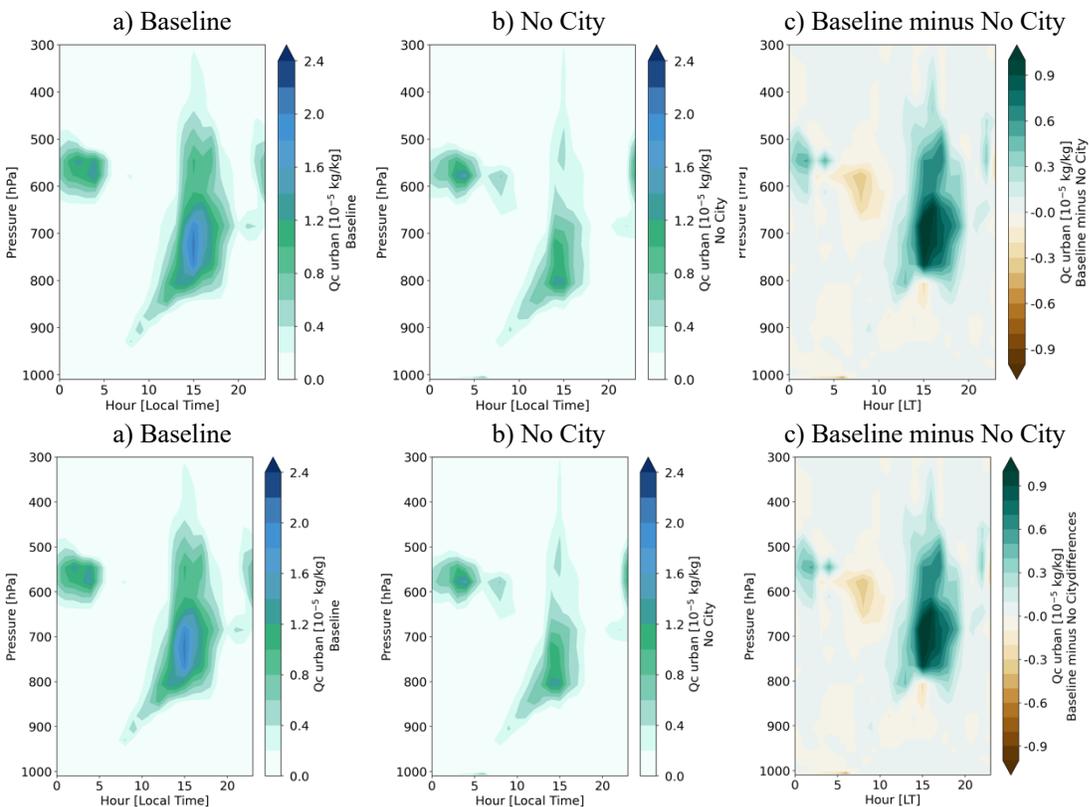

**Figure 8.** Diurnal-pressure mean urban cloud mixing ratio for a) Baseline, b) No City and c) Baseline minus No City scenarios differences. Urban grid points selected according to MODIS/WUDAPTv2 land use/land cover types.

Figure 9 shows that the cloud base is significantly higher and thicker in the urban layer dome. Compared to the rural areas, an increase in cloud base height is expected in environments with lower relative humidity (Williams et al. 2015) or higher Bowen ratio (Chiu et al. 2022). Additionally, it is possible that the thicker mixed layer is favored by enhanced surface temperature, leading to enhanced sensible heat flux (Fig. 5), and by the apparent increase in urban aerodynamic roughness exhibited as a deceleration of the predominant south-southeasterly low-level wind over the urban area (Fig. 10). Notably, the urban PBL diurnal differences increase linearly after sunrise, but are damped around the time of maximum shallow cumulus (~15 LT), in which the enhanced clouds control a transient surface cooling effect and sensible heat flux reduction (Fig. 5), hence temporarily lowering the vertical mixing.
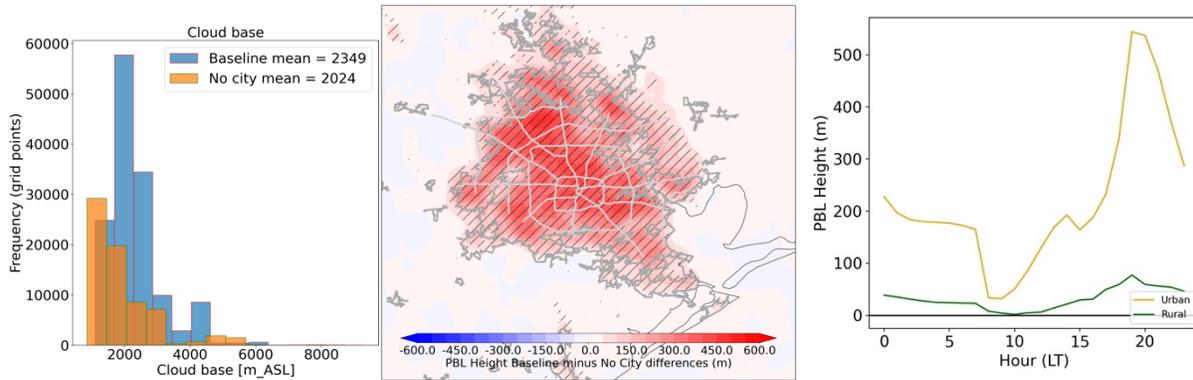

417

418 **Figure 9.** (Left panel) Cloud base distribution for the Baseline and No City scenarios over the urbanized area.
419 Student's t-test and Kolmogorov–Smirnov test indicate that means and distributions are significantly different with
420 99% confidence level. (Middle panel) Baseline minus No City PBL height differences with hatched areas indicating
421 that differences are significant with a 95% confidence level; Dark grey contours indicate urbanization boundaries as
422 of 2010 (Houston-Galveston Area Council, H-GAC; https://www.h-gac.com/Home) and light grey show location of
423 major intraurban highways. (Right panel) Baseline minus No City PBL height differences averaged over urban and
424 rural areas.

425

426       To better understand the factors driving enhanced clouds over the urban dome, we

427 examined the diurnal-height urbanization impacts for various dynamical and thermodyncamical

428 parameters, using composites of the Baseline minus No City scenarios (Fig. 11). Synchronous

429 with enhanced afternoon uplift, the urban dome extends up to ~2 km with a dipole of warmer and

430 drier airmass over the city and cooler and moister air mass in the upper-mixing layer. A

431 significant feature in Fig. 11 is that the mixed layer air entering the afternoon shallow cumulus

432 clouds is related to enhanced Moist Static Energy (MSE), suggesting that the clouds convective

433 updrafts (Fig. 11b) are dominated by the warmer temperature (Fig. 11a) and increased sensible

434 heat flux near the surface, as well as enhanced water vapor in the upper-mixed layer (Fig. 11c).

435 Dynamically, the enhanced water vapor air masses are sustained by the increases in both

436 horizontal moisture flux convergence at low-levels and upward moisture flux convergence in the

437 upper-mixed layer.  Additionally, an urban-induced circulation cell with northerly low-level and

438 south-southwesterly upper-mixed layer circulation disturbance (and enhanced moisture flux

439    divergence) is revealed. This circulation pattern in the urban dome resembles the self-contained

440    UHI circulation described by Fan et al. (2017). Moreover, Fig. 10 highlights the horizontal extent

441    of the low-level branch of this circulation, impacting beyond the urban area and well

442    downstream of the city.

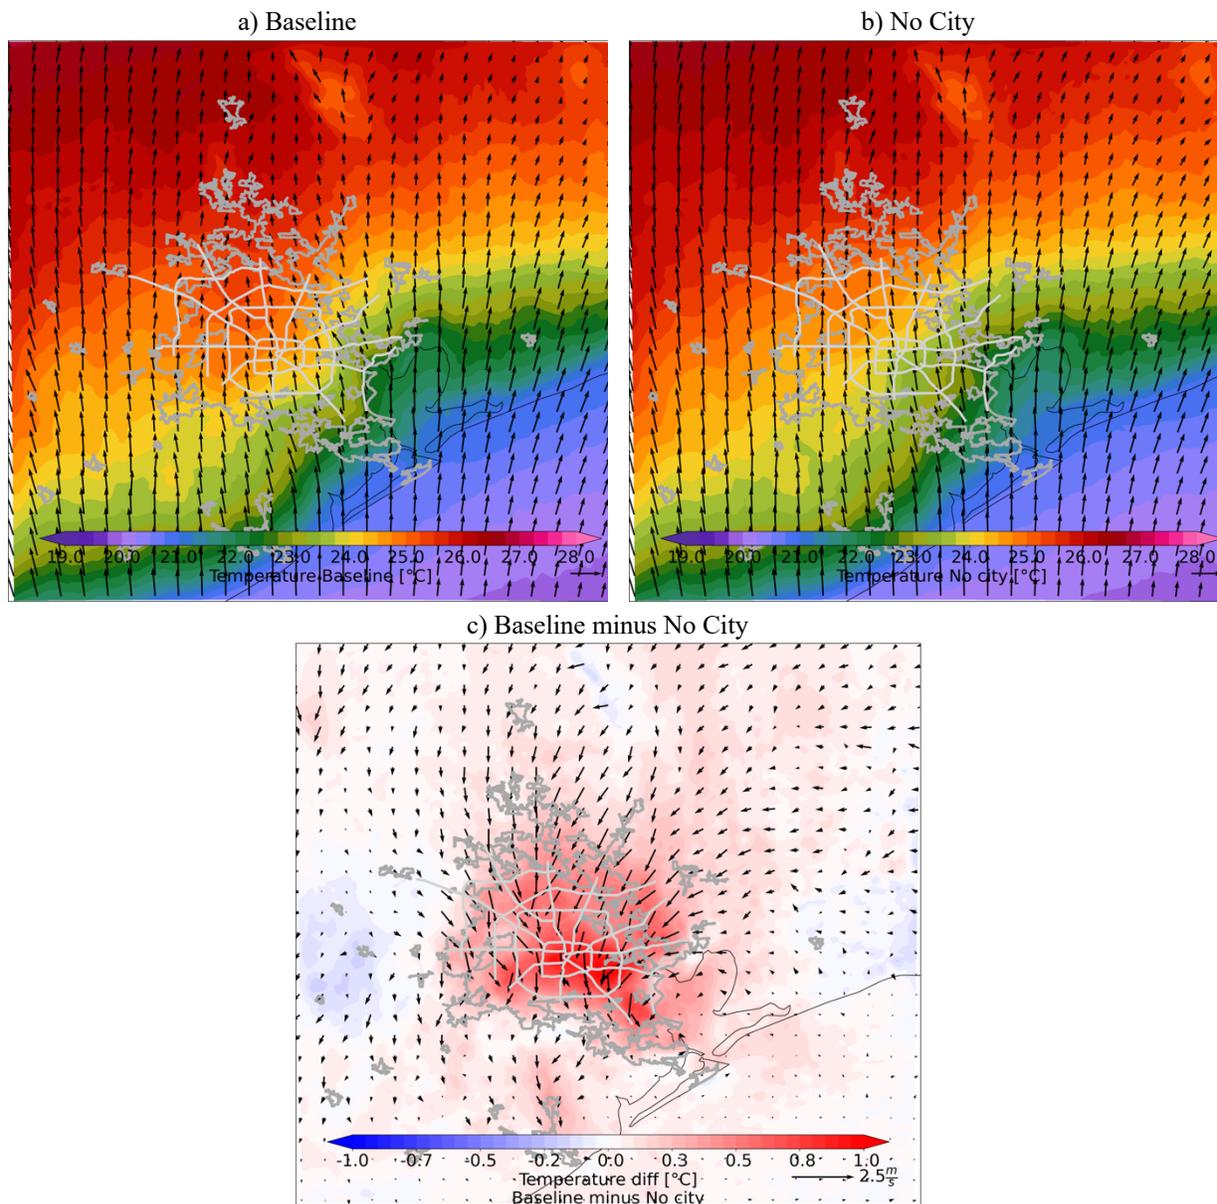

**Figure 10.** 500 m (above MSL) temperature and wind vectors for (a) Baseline, (b) No City and (c) Baseline minus
No City differences averaged between noon and 18 LTC. Dark grey contours indicate urbanization boundaries as of
2010 (Houston-Galveston Area Council, H-GAC; https://www.h-gac.com/Home) and light grey show location of
major intraurban highways. ). Wind vectors are plotted only every 6 grid points to avoid cluttering.

447
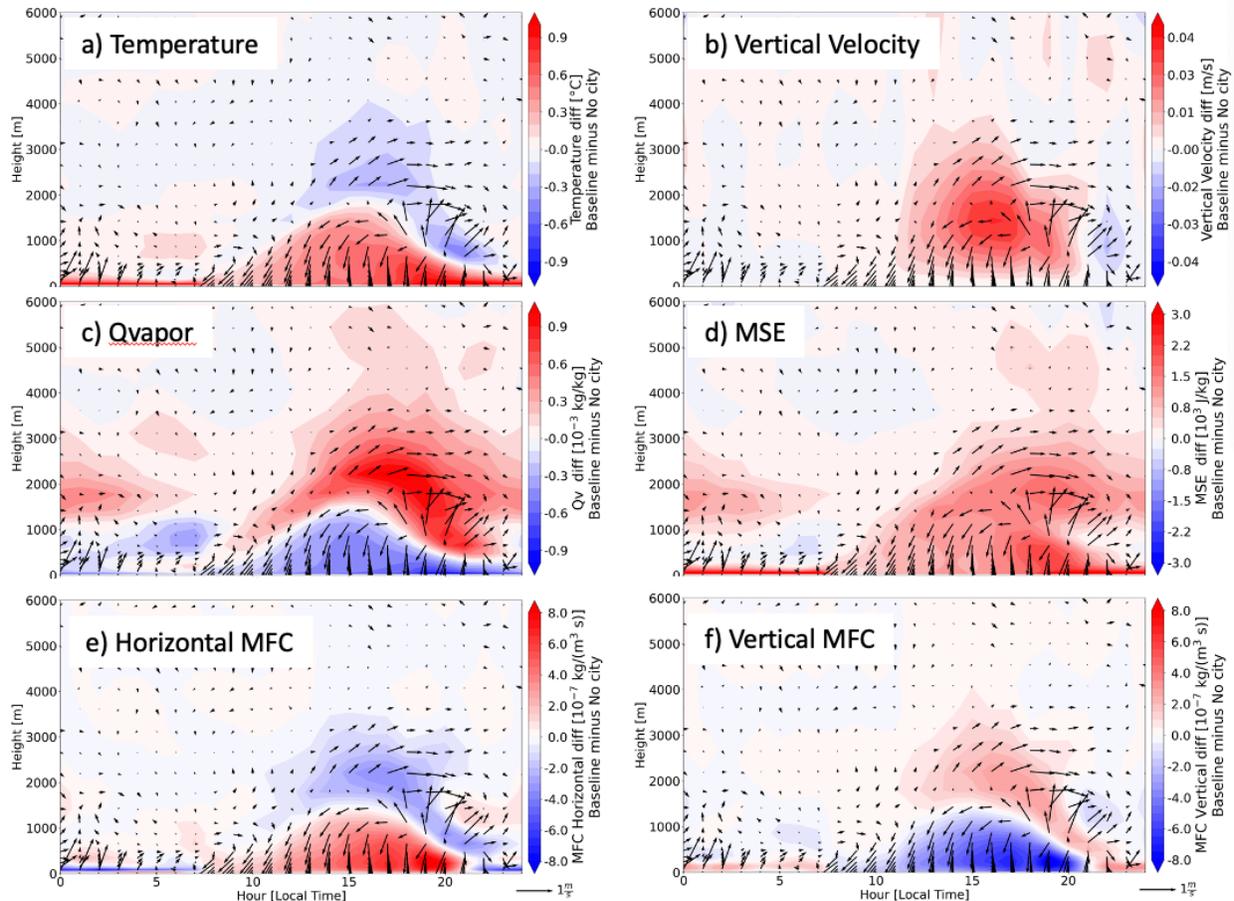

**Figure 11.** Diurnal-height Baseline minus No City scencario differences spatially averaged over the urban areas for (a) air temperature, (b) vertical wind component, (c) water vapor mixing ratio, (d) moist static energy (MSE), (e), horizontal moisture flux convergence, and (f) vertical moisture flux convergence. Vectors in each panel correspond to the horizontal wind, with the north direction pointing upwards. In the vertical, wind vectors are plotted only every 6 grid points to avoid cluttering. MSE = $C_p.T + g.z + L_v.q$, where $C_p$ is the specific heat at constant pressure, T is the air temperature, g is the gravitational constant, z is the geopotential height above MSL, $L_v$ is the laten heat of vaporization, and q is the specific humidity.

It is possible that shallow cumuli and enhanced precipitation (not shown) moisten the cloud and subcloud layers, further favoring more cloud development. Fig. 12 displays a bulk mixing line analysis with the thermodynamical structure of conserved variables (potential temperature and water vapor mixing ratio) in the subcloud and surface layers. The enhanced frequency in entrainment and downdrafts zones in the Baseline relative to the No City simulation further suggest more active cloud dynamics. Notably, when compared to the No City simulation,

461     the Baseline simulation shows that surface fluxes predominantly provide a warmer and dryer

462     mixing lines, with enhanced downdrafts moistening and cooling the subcloud layer. The

463     enhanced cloud downdrafts help explain the layer of relatively cool air above the urban heat

464     island dome shown earlier (Fig. 11a). Furthermore, the Baseline simulation also shows more air

465     masses with warming and drying turbulent entrainment from the free atmosphere into the

466     subcloud layer.  Thermodynamically, the enhanced MSE in the subcloud layer (Fig. 11d) is then

467     predominantly maintained by enhanced enthalpy from the surface zone, and partly enhanced by

468     evaporation of the downdrafts and turbulent entrainment.  A MSE budget can reveal the

469     proportion of MSE fluxes from each zone, but we refrained to further diagnose the zone

470     contribution fraction because by construction, the non-local closure PBL scheme used in our

471     modeling setup limits a detailed characterization of the mixing lines within the mixed and

472     subcloud layers.

a) Baseline          b) No City          c) Baseline minus No City

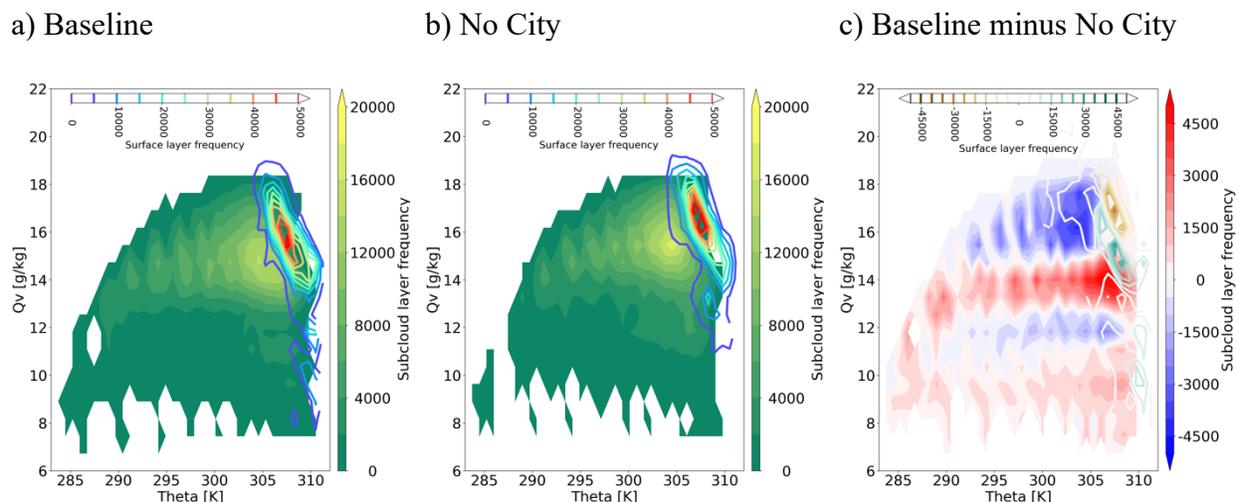

473     **Figure 12.** Mixing line potential temperature and water vapor mixing ratio frequency distribution analyses for
474     (shaded contours) subcloud and (contour) surface layers over the urban area for (a) Baseline, (b) No City, and (c)
475     Baseline minus No City. Only urban grid points in the 12 to 16 LT period were considered.

## 3.4 Sea-Breeze and Urban Induced Circulations

476

477        To test the sensitivity of the urban clouds against regional sources of moisture and

478 mesoscale circulations related to the land-sea contrast, we compared the Baseline with the Biased

479 SST simulations. Fig. 13 shows that the warm SSTs adjustment in the Baseline simulation favors

480 more shallow cumulus clouds.  The effect of urbanization, however, is still dominant when

481 compared to the warm SSTs adjustment.  Notwithstanding is that the warm SSTs adjustment also

482 increases clouds over the rural areas (not shown). By construction, the warmer SSTs develop a

483 warmer low-level atmosphere, with increased latent heat fluxes and water vapor, that in turn, are

484 advected by the predominant southerly and southeasterly flow (Figs. 3, 10).  Fig. 14 shows

485 evidence of warming and moistening over the city, with some striking asymmetries in relation to

486 the changes in local circulation and the clouds themselves.   The increased water vapor and

487 temperature are related to the more intense MSE signal, which favors a thermodynamical

488 pathway for the enhancement of clouds due to a more unstable lower troposphere, with an

489 enhanced, but weaker relative to the Baseline minus No City,  horizontal MFC support.  Notably,

490 the urban area shows a low-level cooling and moistening signal concurrent with the enhanced

491 clouds, further displaying the role of the urban clouds and subcloud layer processes in the

492 daytime UHI effect.

493

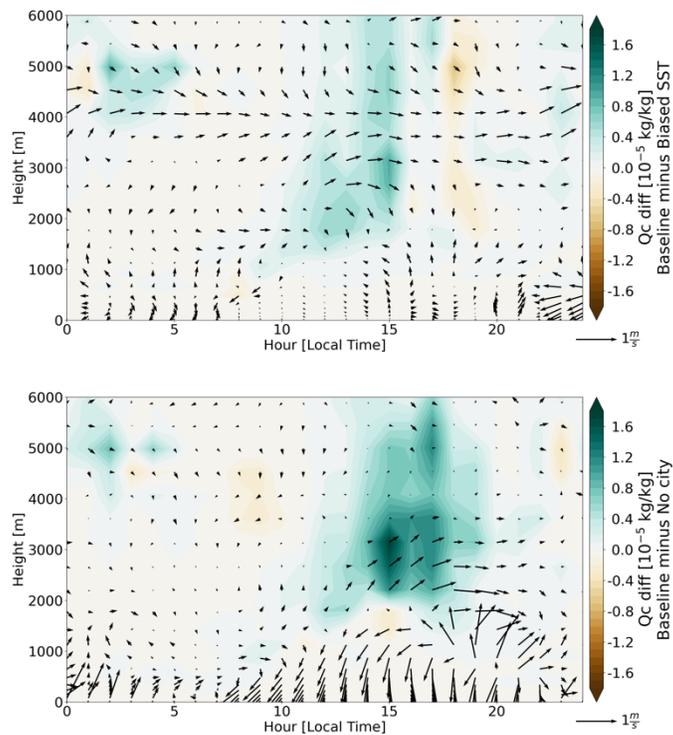

494
495 **Figure 13.** Diurnal-height Cloud mixing ratio and wind vector differences spatially averaged over the urban areas

496    for (top panel) Baseline minus Biased SST and (bottom panel) Baseline minus No City. Vectors in each panel

497    correspond to the horizontal wind, with the north direction pointing upwards).

498        To better display the impact of the No City and Biased SSTs in the mesoscale

499    circulations, Figs. 15 and 16 show 6-hour averaged diurnal time slices for both interpolated fields

500    at 500 m height and latitude-height slices across the city (Fig. 1c).  The Baseline minus No City

501    differences show that the urban circulation dome is emphasized as the warm blob collocated with

502    the northerly wind differences. Earlier results showed that this urban circulation dome is favored

503    by the enhanced sensible heat flux, increasing the urban-rural thermal gradient and vertical

504    mixing over the city, and the dynamic frictional drag.  Of note is that urbanization imposes

505    anticyclonic and cyclonic differences to the west and east of the city core, respectively, with a

506    horizontal scale as large as the urbanization scale and extending vertically as high as 3500 m

507    above MSL (Fig. 15; Fan et al. 2017).  The urban circulation dome seems to dominate the

508    circulation difference, obscuring impacts on the bay- and sea-breeze circulation that have been

509    reported in the literature (Ryu et al. 2016; Shen et al. 2018; Fan et al. 2020; Wang et al. 2023).

510         The impact of warmer SSTs in the Baseline simulation shows an enhancement of the

511    evening-to-morning land-breeze and a weaker sea-breeze (Fig. 15), which agrees with previous

512    SST sensitivity studies (Ryu et al. 2016; Chen et al. 2011). Characterizing the timing and

513    intensity of the sea breeze in the Houston-Galveston area is complicated by the costal shapes and

514    SST differences with a relatively warmer Galveston Bay as compared to the Gulf of Mexico

515    (Salas-Monreal et al. 2018).  However, Fig. 16 shows that the weaker sea breeze cell favors the

516    weaker moisture transport near the surface and augments the southerly-southeasterly flow in the

517    return branch of the cell, which help describe the moist difference over the urban area (Fig. 14c).

518    Additionally, the enhanced offshore sensible and latent heat fluxes in the Baseline simulation

519    help develop a deeper and moister marine boundary layer (not shown), further enhancing the

520    transport of water vapor by the background wind and in the return branch of the sea-breeze.

521
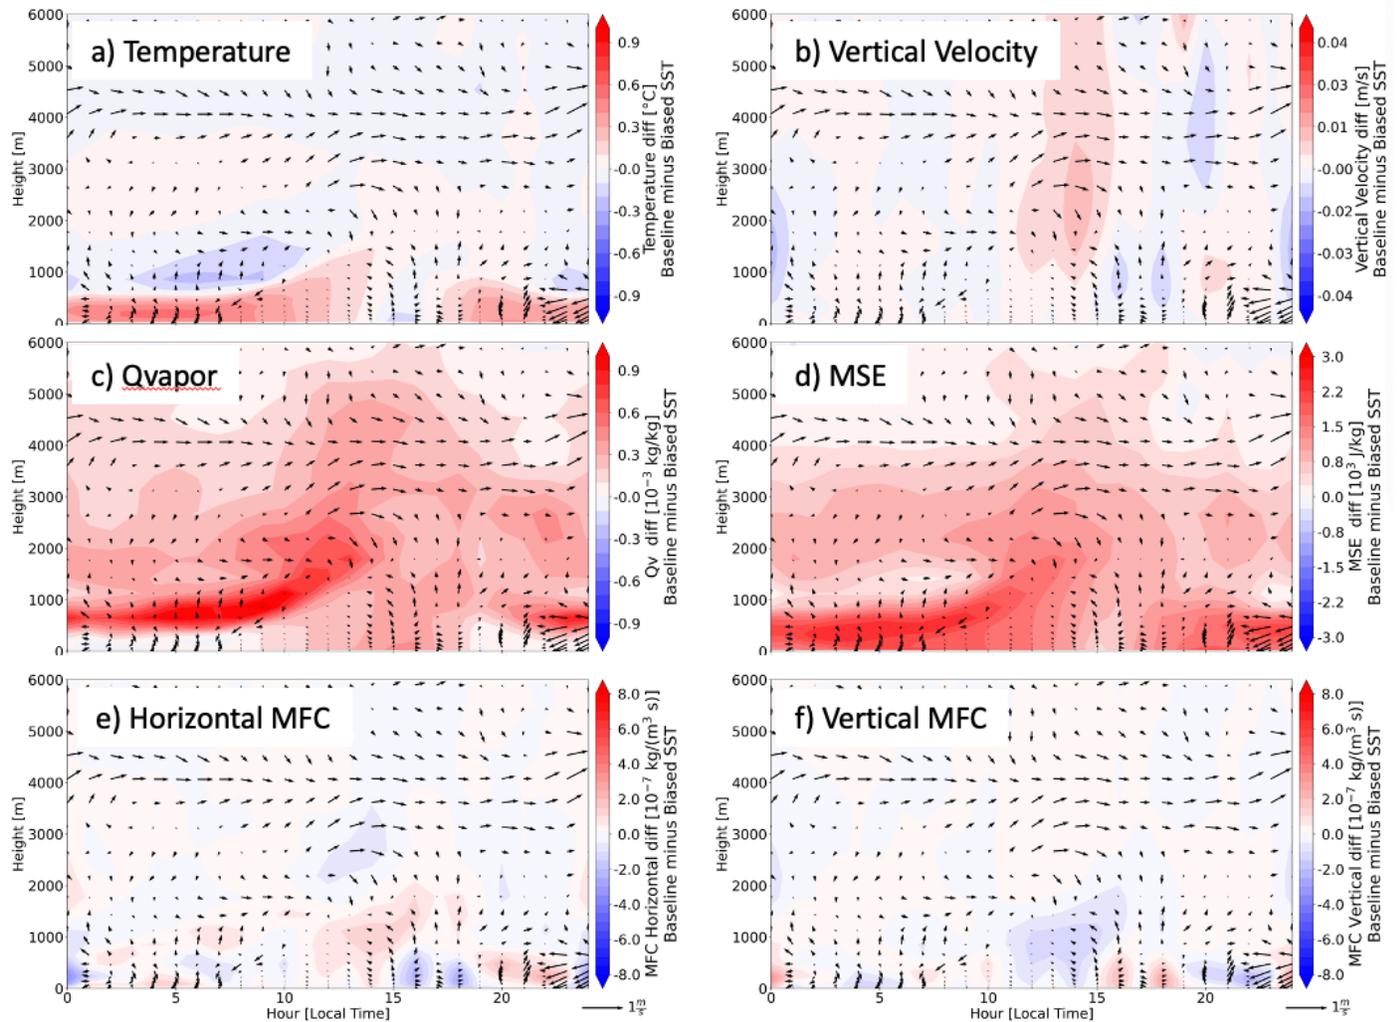

**Figure 14.** Same as Fig. 11 but for Baseline minus Biased SST scencario differences. Vectors in each panel
correspond to the horizontal wind, with the north direction pointing upwards. Wind vectors are plotted only every 6
grid point to avoid cluttering.

## 3.5 Heat Index Sensitivity

Here, we examine the role of urbanization, clouds, and SST uncertainties in the Heat
Index. Fig. 2 indicated that the model has some limitations in simulating the amplitude of the
diurnal cycle of the HI over both rural and urban areas, overemphasizing the HI during the
nighttime and underemphasizing the HI during the daytime. Although these diurnal biases can
be traced to a low performance in simulating relative humidity, more work is needed to assess
the model limitations and sources of uncertainty in stimating the HI. By contrasting the model

532    simulation scenarios, however, we can partly cancel these biases (i.e., linearizing the potential

533    effect of internal feedbacks) and retain the signal related to urbanization, clouds and SST in the

534    diurnal evolution of the HI.

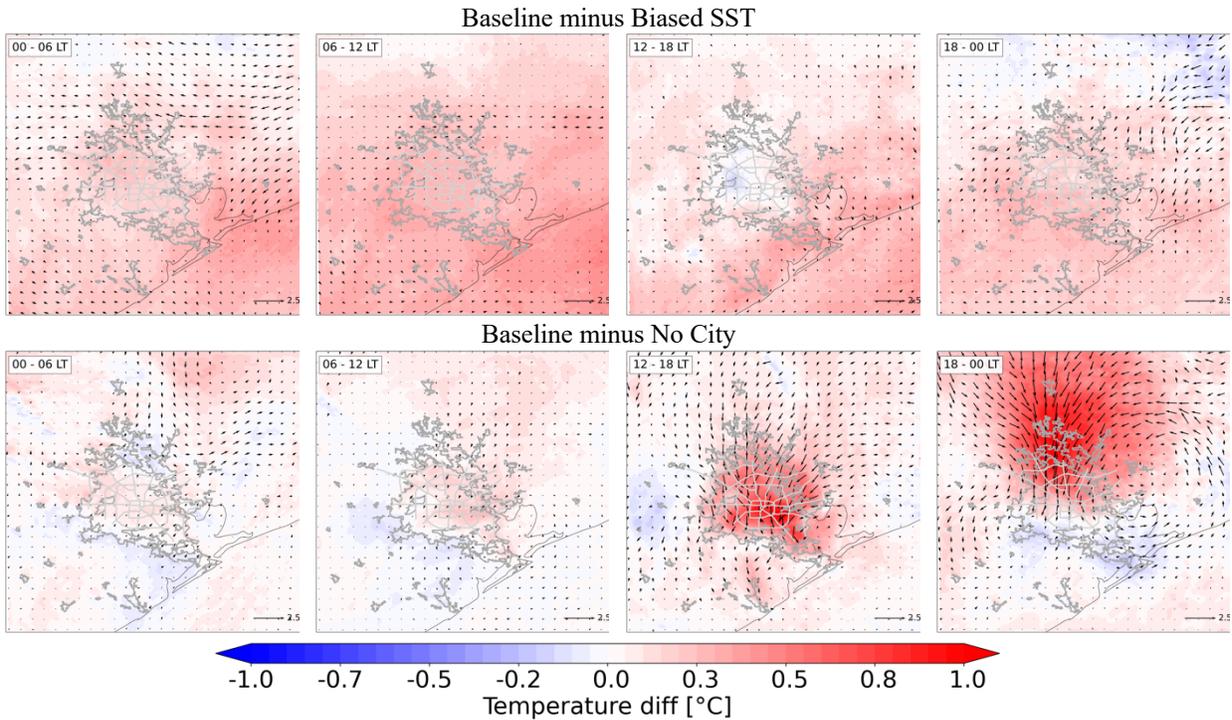

535    **Figure 15.** 500 m (above MSL) height air temperature (contours) and horizontal circulation (vectors) for (top

536    panels) Baseline minus Biased SSTs and (bottom panels) Baseline minus No City differences, diurnally averaged

537    over 6-hour time slices (upper left corner in each panel; Local Time). Wind vectors are plotted every 10 grid point to

538    avoid cluttering. Dark grey contours indicate urbanization boundaries as of 2010 (Houston-Galveston Area Council,

539    H-GAC; https://www.h-gac.com/Home) and light grey show location of major intraurban highways.

540
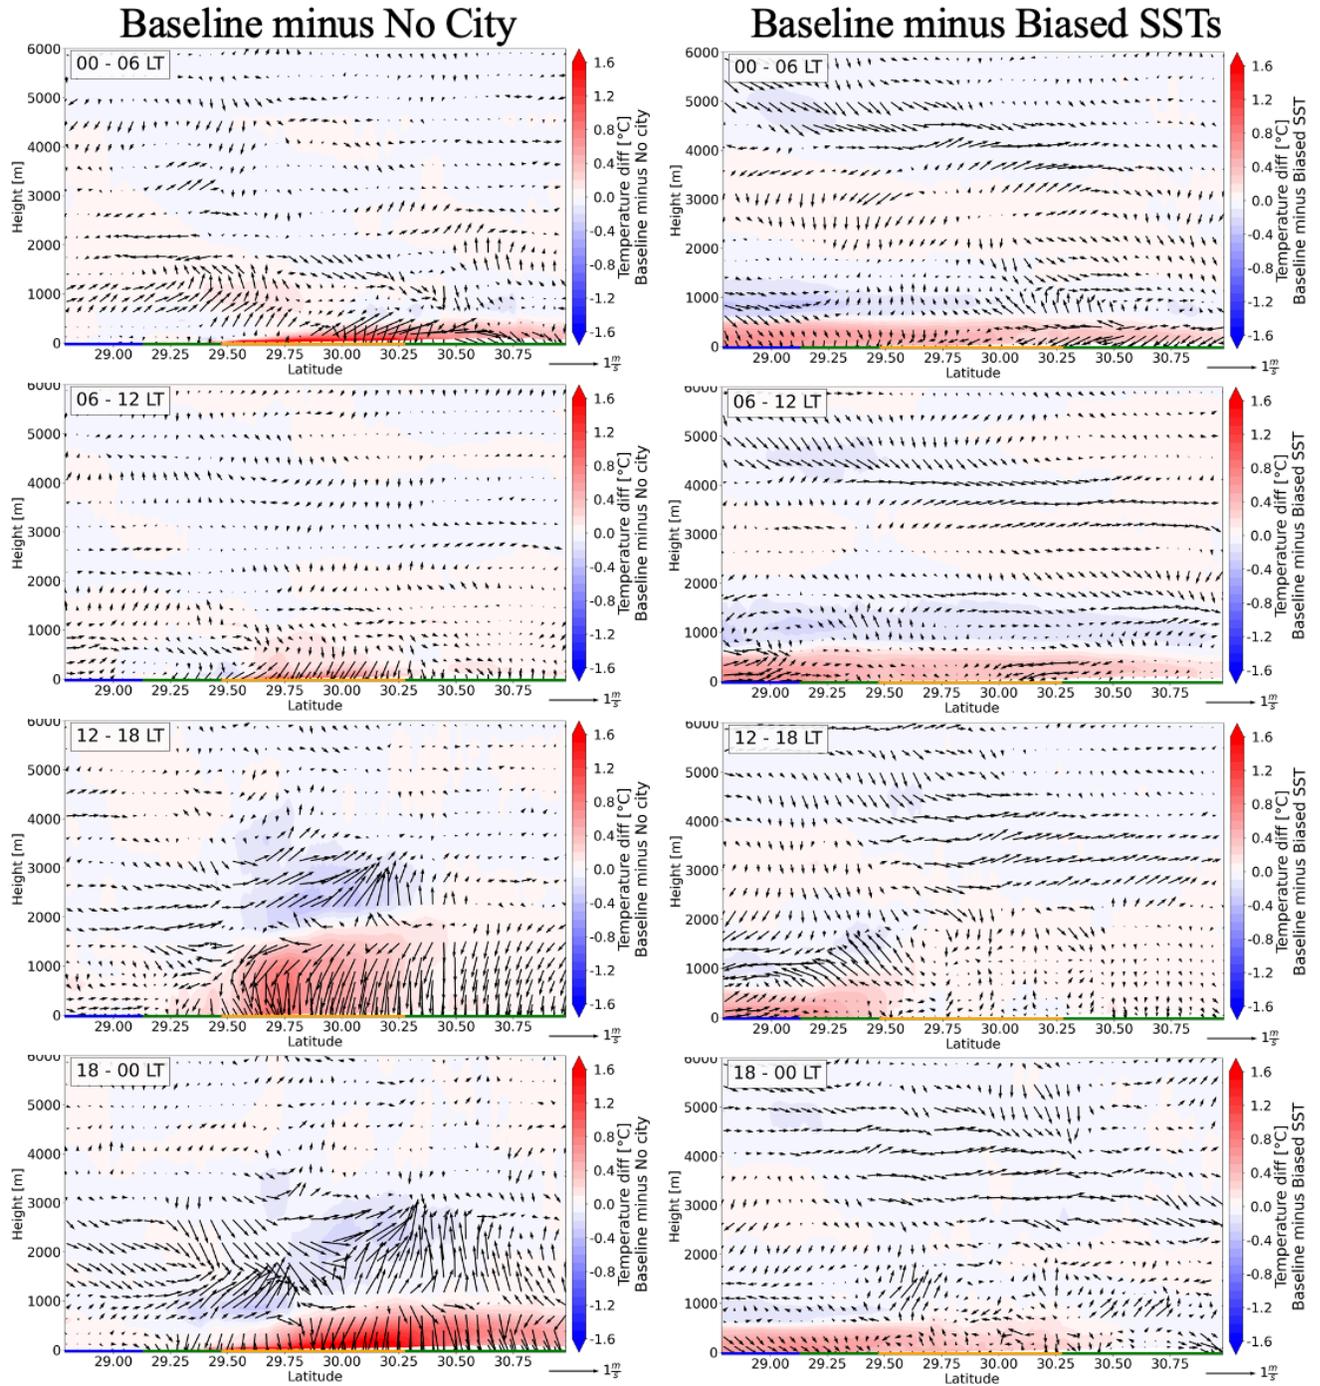

**Figure 16.** Diurnal evolution (top to bottom) of latitude-height temperature and wind vectors for Baseline minus No

City and Baseline minus Bias SST analyses along transect displayed in Fig. 1, with colored lines at the bottom of the

panels indicating the location of water (blue line), rural (green lines) and urban areas (orange line). Vectors in each

panel correspond to the horizontal wind, with the north direction pointing upwards.

546    Figure 17 shows the sensitivity of the HI to urbanization and SST adjustments.  On the

547    mean, the UHI has a significant influence in increasing the HI, mostly during the nighttime and

548    early morning.  During high HI times (around 15 LT), however, urbanization is related to weaker

549    HI compared to the rural areas, due to the competing impacts of air temperature and relative

550    humidity on the HI. Over the city, the weaker high HI is partly due to the urban dry island effect

551    (Fig. 5c), and partly due to enhanced clouds and its surface cooling effect (Fig 8), limiting high

552    temperatures in the city (Fig. 6).  The sensitivity of the HI to moisture is also shown when

553    contrasting Baseline with the Biased SST simulation.  Fig. 17 also shows that the warmer SSTs

554    (~1°C) impact the mean HI with a more intense effect near the coast and over the urbanized

555    areas.  During high HI, the HI impact of the warmer SSTs over the urban area is less apparent,

556    likely due to the cloud surface cooling effect balancing the warmer and moist sea breeze (Fig.

557    14).

## 4   Discussion and Conclusion

559    To better understand the effect of urbanization in meteorology over the Houston-

560    Galveston area, this study developed 900 m  grid size simulations between 1-16 August 2020

561    using a cloud- and urban-resolving atmospheric model that includes a Building Energy Model

562    coupled with Building Effect Parameterization.  The study investigates the intricate interplay of

563    clouds in local weather, considering various influencing factors. Several model realizations were

564    developed to isolate the role of the urban environment and to address SST biases in the complex

565    Galveston Bay and Gulf of Mexico coast and its effect in the land-sea circulations known to

566    affect the urban climate (Chen at al. 2011; Ngan et al. 2013; Fan et al. 2020). By excluding local

567    anthropogenic aerosols and their effects, this research provides deeper insights into the

568   relationship between the city and shallow cumulus clouds. These insights contribute to our

569   understanding of the processes modulating excessive heat indicators over urban environments.

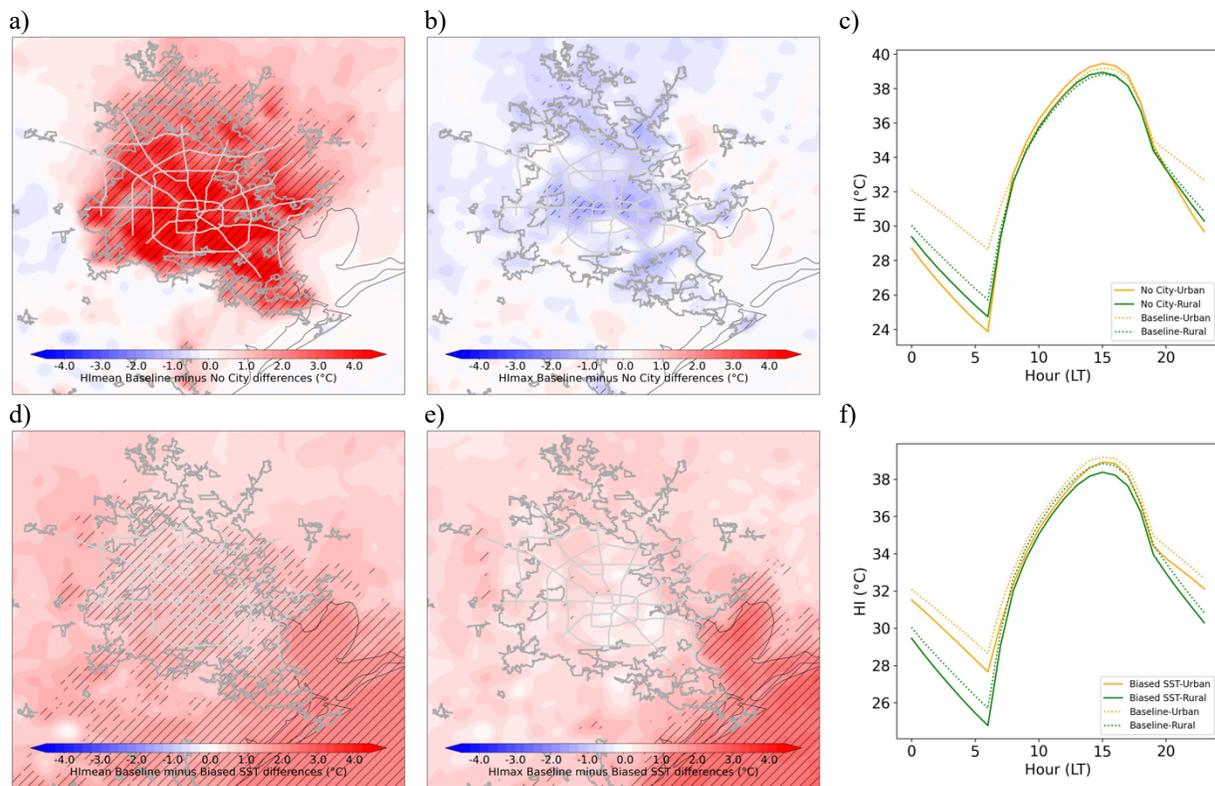

570   **Figure 17.** *Diurnal mean and maximum Heat Index (HI) differences for Baseline minus No City (a, b, respectively)*
571   *and Baseline minus Biased SST (d and e, respectively). Hatched areas indicate that differences are significant with a*
572   *95% confidence level; Dark grey contours indicate urbanization boundaries as of 2010 (Houston-Galveston Area*
573   *Council, H-GAC; https://www.h-gac.com/Home) and light grey show location of major intraurban highways. HI*
574   *diurnal variability composited by rural and urban areas is also added for (c) Baseline and No City and (f) Baseline*
575   *and Biased SST.*

576       Through comprehensive model evaluation using 150 surface station sites, an upper-air

577   wind profiler and a cloud climatology, our analyses reveal that the model simulations perform

578   adequately, but common and well-documented biases remained. In agreement with Ngan et al.

579   (2013), the model overestimates southerly winds by overemphasizing the nighttime low-level jet.

580   However, the model also simulates a stronger sea breeze, which is somehow consistent with the

581   urban warm surface temperature bias (Fig. 2), and in turn can favor a more intense temperature

582   gradient during the late evening and early morning and maintaining the onshore see-breeze flow

583    much longer. Likewise, the warm nighttime temperature bias could be partly related to the

584    outlined biased low-level southerly winds by favoring a larger temperature advection from the

585    offshore waters into land and the urban areas.  All results and conclusions relying on advection

586    of environmental parameters, including air pollution constituents (Ngan et al. 2013), into or

587    downstream the city need to be assessed with caution. For example, the downstream extend of

588    the UHI impact to the north and northeast of the city may be overemphasized in this model

589    results due to the strong wind bias. Over rural areas, the warm and dry bias could be related to

590    over advection of the UHI and urban dry island effects (Qian et al. 2022; Fig. 4). The bias

591    differences between the urbanized (Baseline) and the No City simulations show that the city is

592    modulating the surface temperature errors, even over the rural areas (UHI advection and UHI

593    dome and related circulations).  On the other hand, Fig. 3d shows that the model simulates a

594    weaker sea-breeze at La Porte when compared to the No City scenario. Previous studies suggest

595    that the enhanced drag imposed by the city decelerates the flow (Chen et al. 2011; Salamanca et

596    al. 2011; Barlow 2014), which we showed reduces the impact of the enhanced thermal driven

597    land-sea circulation due to the warmer city (Fig. 10 and Fig. 15).

598         It has been suggested that the UHI is more pronounced during the nighttime (Oke 1982),

599    but recent studies have found asymmetries in the time of the maximum diurnal UHI effect,

600    arguing that vegetation type, urban and rural activities (Peng et al. 2012), or clouds (Vo et al.

601    2023) can affect the time of its maximum.   Surface station estimates suggest that during the

602    period of study, the UHI was more intense during the afternoon than during the morning,

603    whereas the model suggested the opposite when evaluated at the same surface station locations.

604    This UHI intensity disagreement is common when comparing surface station observations with

605    urban canopy model output (Hu et al. 2019; Venter et al. 2021; Qian et al. 2022).  However,

606 estimating the magnitude of the UHI based on surface station observations is a challenging task,

607 including observational uncertainty issues related to limitations of urban stations in following

608 footprint standards (WMO 2008). Moreover, we noted that the magnitude of the UHI is more

609 pronounced farther from the coast, but also varies according to the location of the rural stations

610 relative to the predominant low-level flow, due to the outlined advection of heat downstream

611 from the city. Our results show the typical ground heat flux driving the nighttime UHI, but other

612 meteorological factors became apparent when considering the interaction with mesoscale

613 circulations and clouds. During the afternoon, we speculate that the smaller simulated diurnal

614 UHI can include possibly the overdoing of the urban clouds, limiting temperature highs in the

615 afternoon, asymmetries in the biases between urban and rural sites, among other model

616 deficiencies. During the nighttime, urbanization enhanced uplift water vapor and clouds slow

617 down the nighttime longwave radiation cooling.

618 Houston-Galveston urbanization favors more shallow cumulus clouds. Our modeling and

619 satellite results support Vo et al. (2023) by showing an apparent cloud enhancement due to

620 urbanization. The simulation period for this study coincides with the time of the year when the

621 urbanization cloud patterns are the largest for Gulf Coast coastal cities (Vo et al. 2023). These

622 results agree with Loughner et al. (2011) and Theeuwes et al. (2019) hypothesis that even over

623 urban areas with relatively drier environments, the surface-driven turbulence can sustain longer-

624 lasting clouds compared to the surrounding rural areas. Despite the model uncertainties and

625 biases shown and discussed above, and without considering the role of aerosols, which play a

626 crucial role in the cloud and precipitation invigoration (Fan et al. 2020) in urban environments,

627 our results help understand the mechanistic processes involved in the urban cloud enhancement.

628 Particularly, our simulations confirm the control of the UHI in the clouds by enhanced vertical

629    mixing due to aerodynamical drag and an enhanced sensible heat as compared to the surrounding

630    rural areas. In addition, our results also offer a deeper insight on the dynamical and

631    thermodynamical factors interplaying in the cloud enhancement.  The city sustains more clouds,

632    with higher cloud heights and deeper shallow cumulus owing to enhanced moist static energy,

633    partly due to enhanced enthalpy by the surface sensible heat and partly due to the enhanced latent

634    heating favored by a stronger low-level horizontal moisture flux convergence (Loughner et al.

635    2011; Fan et al. 2017; Theeuwes et al. 2022; Chiu et al. 2022). We showed that more clouds, in

636    turn, are related to a cooler surface temperature maximum, when compared to the No City

637    environment and the surrounding rural areas. This cooling can further reduce the afternoon

638    urban-rural heating contrasts and suppress vertical mixing. However, our mixing line analysis

639    also shows that part of this cooling can also be attributed to evaporative cooling downdraft

640    fluxes. Notwithstanding, enhanced MSE is predominantly maintained by the surface heat fluxes,

641    with a minor role from the warm air entrainment fluxes.  All these mechanisms also help

642    understand the precipitation enhancement associated with urbanization (SFig. 4; Ryu et al. 2016;

643    Zhu et al., 2016; Lorenz et al. 2019; Statkewicz et al. 2021; Fan et al. 2020, Chiu et al. 2022;

644    Wang et al. 2023) and aerosol-cloud interaction and air pollution impacts (Loughner et al. 2011;

645    Seigel 2014; Fan et al. 2020; Zhong et al. 2015, 2017; Caicedo et al. 2019), which are ongoing

646    observational and modeling research foci (Jensen et al. 2022).

647        For the first time, our results suggest that the enhanced drag, sensible heat, and vertical

648    mixing related to urbanization act as an obstacle to the prevailing flow, favoring urban

649    circulation dome patterns with a horizontal scale of influence as large as the urban area. Previous

650    studies have suggested that the UHI circulation can strengthen the sea breeze circulation, which

651    favors moisture flux convergence and cooler airflow into the urban environment (Ryu et al.

652   2016; Zhong et al. 2017; Shen et al. 2018; Fan et al. 2020). However, our results show that

653   dynamical frictional drag due to urbanization slows down the low-level flow with a scale of

654   influence that appears to weaken the thermal-driven bay- and sea-breezes influencing the city. It

655   is possible that deceleration from the urban dynamical drag effect becomes less prominent, and

656   the urban land effect on the sea breeze circulation can become more evident, during weaker or

657   different south-southwesterly background flow regimes (Chen et al. 2011; Ngan et al. 2013;

658   Wang et al. 2022).

659        Urbanization increases the mean HI, the maximum HI is less intense in the urban area of

660   the Baseline, due to the cloud enhancement pathway as a cooling mechanism.  Additionally, the

661   model sensitivities to SSTs revealed that the coastal environment can modulate the UHI

662   intensity, with warmer SSTs producing cooler urban surface temperature highs due to a similar

663   enhanced shallow cumulus cloud pathway, despite the weaker but warmer and moist sea-breeze.

664   Near the coast, the effect of the warmer and more humid environment (due to the warmer SSTs)

665   advected by the sea-breeze appears to have a net intensification of the urban HI, but the

666   maximum HI does not show significant sensitivity, likely due to the competing factors between

667   the surface temperature and relative humidity. These results offer new insights and complement

668   other studies focusing on urbanization and related modulation of the sea breeze as driving

669   mechanisms of the urban heat stress and pollution transport problems in cities near large surface

670   water bodies (Shen et al. 2018; Caicedo et al. 2019; Wang et al. 2023).

671        Modeling work aiming to assess the impact of heat adaptation and mitigation strategies

672   need to assess the tradeoffs in the UHI circulations and clouds pathways relationships. Most

673   mesoscale urban heat mitigation modeling studies suggest different cooling strategies influencing

674   city scale net cooling effects ranging from ~0.1 to a few degrees °C, depending on the intensity

675    of the implementation (Krayenhoff et al. 2021), but often assume that model biases and other

676    errors are somehow steady under different model conditions and disregard the effect of model

677    errors on relevant physical process.  Hence, the impact of cooling strategies can be overwhelmed

678    by uncertainties in SST fields (i.e., those related to observations and data assimilation

679    uncertainties), or by the accuracy of the simulated clouds and precipitation, which is typically an

680    important source of uncertainty in the model.

681

691    **Open Research**

692    **Surface Station Data**: All the observational data needed to develop this study is readily

693    available online.  This research utilized weather observations from NWS, RAWS, TCEQ, CAMS

694    networks and were obtained using the Synoptic Data PBC Mesonet API (free access to the data

695    via https://mesowest.utah.edu/); buoy implemented is readily accessible in the NOAA data portal

696    (https://www.ndbc.noaa.gov/).

697     **Wind Profiler Data**: The Cooperative Agency Profilers dataset can be accessed online using

698     NOAA data portal https://madis-data.ncep.noaa.gov/cap/ (last access, 04/02/2024).

699     **The Model**: The Weather and Research Forecasting model (WRF) is freely available and

700     maintained by the UCAR/National Center for Atmospheric Research

701     (https://www2.mmm.ucar.edu/wrf/users/download/get_source.html) with source version control

702     in the Github portal (https://github.com/wrf-model/WRF/releases).

703     **World Urban Database and Access Portal (WUDAPT; https://www.wudapt.org/)**: Urban

704     Land Cover/Land Use data used in this study were obtained and distributed by Demuzere et al.

705     (2022) and postprocessing code were made available by Brousse et al. (2016).

706     **Sea Surface Temperature (SST) Data**: SST used is based on the Advanced Very High

707     Resolution Radiometer (AVHRR) on the European MetOp satellites, and the Visible Infrared

708     Imaging Radiometer Suite (VIIRS) on the U.S. SNPP and NOAA JPSS satellites NOAA-SNPP

709     VIIRS and readily available online (https://eastcoast.coastwatch.noaa.gov/cw_data_access.php).

710     **Initial and Boundary Conditions**:  The Global Tropospheric Analyses and Forecast Grids a

711     (GDAS/FNL; 0.25 degree) were used as initial and boundary conditions to drive the WRF model

712     and is readily accessible online (https://rda.ucar.edu/datasets/ds083.3/; DOI:

713     10.5065/D65Q4T4Z).

# Supplemental Material

910

911
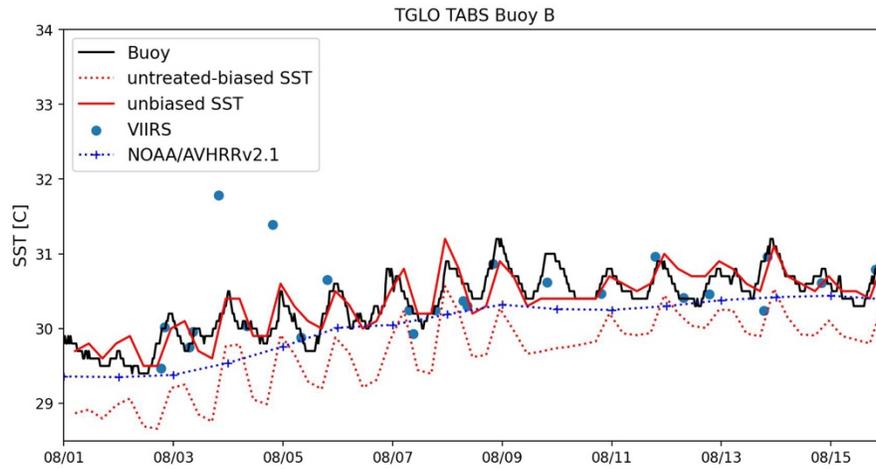

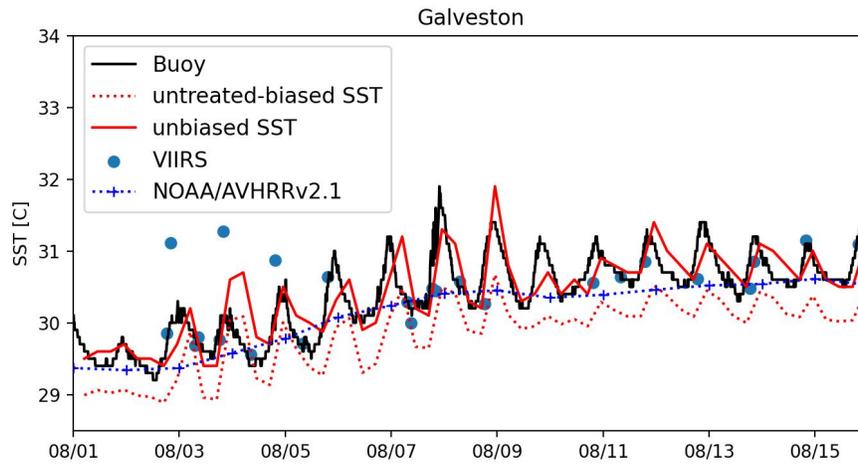

912 **SFigure 1.** (Top panel) TGLO TABS Buoy B and (bottom panel) Galveston hourly buoy SST, twice a day remotely

913 sensed data (NOAA-SNPP VIIRS SST) and untreated-biased SST (after preprocessed by WRF) and biased-

914 corrected or unbiased SSTs. Date (MM/DD) range for the first half of August 2020.
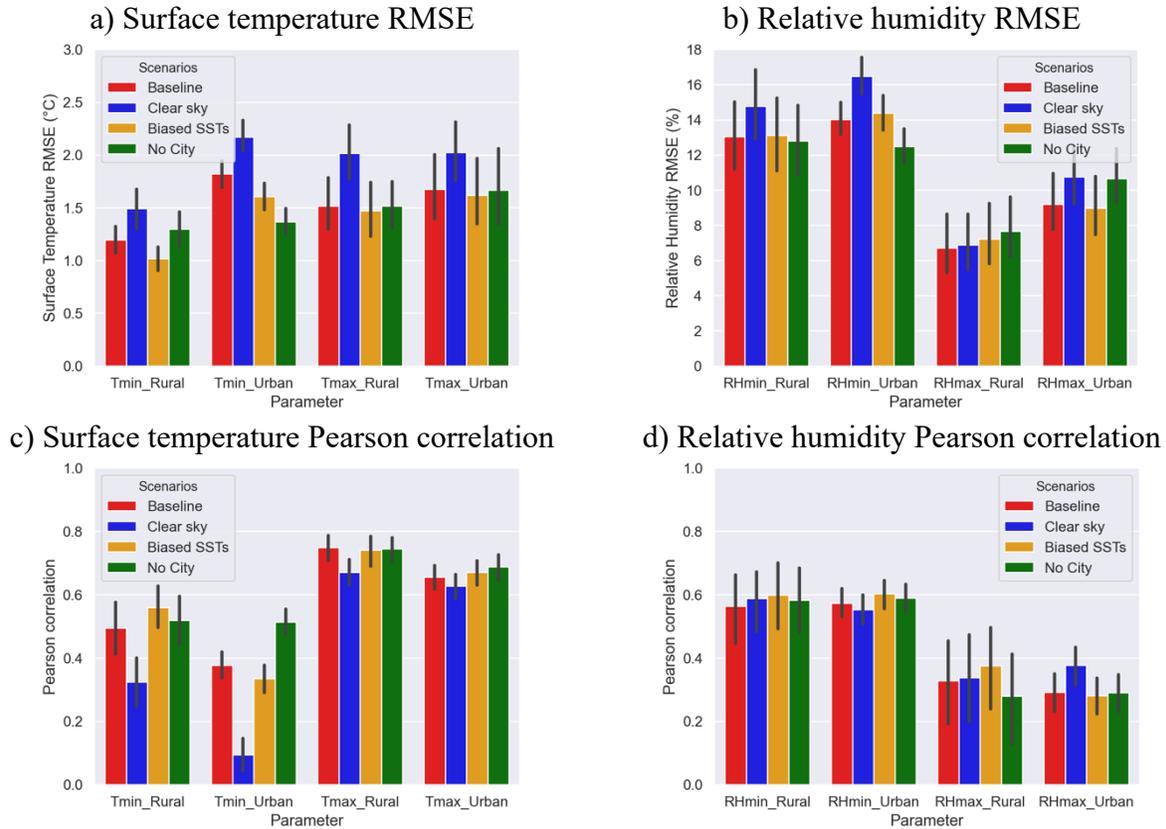

915

916

917

918

919

920

921

a) Surface temperature RMSE
b) Relative humidity RMSE
c) Surface temperature Pearson correlation
d) Relative humidity Pearson correlation

**SFigure 2.** Simulated RMSE and Pearson correlation for evaluated at surface station sites for different scenarios (Table 2) for (a, c) daily for surface temperature low and high (Tmin, Tmax), (b, d) relative humidity maximum and minimum (RHmax, RHmin), and corresponding bias distribution for all examined surface station sites as categorized as Urban or Rural according to MODIS/WUDAPTv2 land use/land cover types. Evaluation period is 1-16 August 2020.  Analysis constrained to non-rainy periods as described in the text.

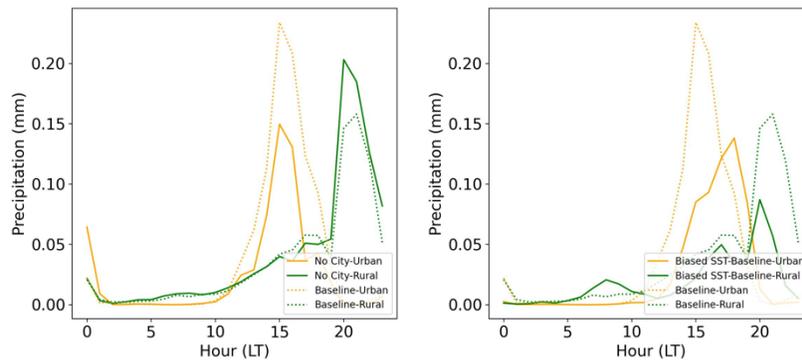

**SFigure 4.** Spatially averaged diurnal precipitation in the urban and rural areas for (left panel) Baseline and No City and (right panel) Baseline and Biased-SST scenarios.
