**Abstract**

Meandering channels are ubiquitous features in intertidal mudflats and play a key role in the eco-morphosedimentary evolution of such landscapes. However, the hydrodynamics and morphodynamic evolution of these channels are poorly known, and direct flow measurements are virtually nonexistent to date. Here, we present new hydroacoustic data collected synchronously at different sites along a mudflat meander located in the macrotidal Yangkou tidal flat (Jiangsu, China) over an 8-day period. The studied bend exhibits an overall dominance of flood flows, with velocity surges of about 0.8 m/s occurring immediately below the bankfull stage during both ebb and flood tides. Unlike salt-marsh channels, velocities attain nearly-constant, sustained values as long as tidal flows remain confined within the channel, and reduce significantly during overbank stages. In contrast, curvature-induced cross-sectional flows are more pronounced during overbank stages. Thus, a phase lag exists between streamwise and cross-stream velocity maxima, which limits the transfer of secondary flows and likely hinders the formation of curvature-induced helical flows along the entire meander length. Our results support earlier suggestions that the morphodynamics of intertidal mudflat meanders does not strongly depend on curvature-induced helical flows, and is most likely driven by high velocities and sustains seepage flows at late-ebb stages, as well as by other non-tidal processes such as waves and intense rainfall events. By unraveling complex flow structures and intertwined morphodynamic processes, our results provide the first step toward a better understanding of intertidal mudflat meanders, with relevant implications for their planform characteristics and dynamic evolution.

## 1 Introduction

Tidal mudflats are among the most extensive coastal ecosystems worldwide (Murray et al., 2019; Murray et al., 2022). They are low-gradient intertidal landforms typically occurring in sediment-rich environments (Gao, 2019; Klein, 1985; Rogers & Woodroffe, 2015) characterized by large tidal oscillations relative to characteristic wind-wave heights (e.g., Friedrichs, 2011; Klein, 1985; Morales, 2022). Tidal mudflats are extremely important from both ecological and economic perspectives thanks to the broad range of ecosystem services they provide (Passarelli et al., 2018), including, nutrient cycling, carbon sequestration, water filtering, habitat provision for wildlife, food production, recreational activities, and cultural services (Choi, 2014; Friedrichs & Perry, 2001; Kim et al., 2000; Kirwan & Megonigal, 2013; Pilkey & Cooper, 2004; Shi et al., 2018; Temmerman et al., 2013; Vousdoukas et al., 2020; Wang et al., 2012).

The morphosedimentary evolution of tidal mudflats is intimately linked to the morphodynamics of the extensive networks of tidal channels that cut through them (Figure 1). These channels are typically meandering in planform to a greater or lesser degree (Choi, 2014; Friedrichs, 2011; Gao, 2019; Hughes, 2012), and play a primary role in regulating the exchanges of water, sediments, nutrients, and biota with the open sea (Coco et al., 2013; D'Alpaos et al., 2005), thus exerting a prominent control on the eco-geomorphology of the tidal-flat ecosystem as a whole (Choi, 2014; Hughes, 2012; Wells et al., 1990). Besides, lateral migration of meandering channels critically affects both the sedimentology and stratigraphy of tidal-flat systems, especially in terms of preservation potential (Choi, 2011; Choi et al., 2013; Ghinassi et al., 2019; Kleinhans et al., 2009). Indeed, mudflat tidal channels are typically preserved in the fossil record either as laterally-accreting, heterolithic point bars or through the infilling of abandoned channels generated either from meander cutoff or channel avulsion (Brivio et al., 2016; Choi, 2010; Cosma et al., 2020; Hughes, 2012; Sisulak & Dashtgard, 2012).

96

97        In spite of their prominence and ubiquity, however, meandering channels in tidal mudflats

98    are still poorly studied especially from a hydrodynamic standpoint. Previous field measurements

99    of flow fields in tidal meanders focused primarily on either tidally-influenced fluvial reaches,

100   where flow dynamics are largely influenced by river discharges and density-stratification effects

101   (Chant, 2002; Keevil et al., 2015; Kranenburg et al., 2019; Somsook et al., 2020), or on intertidal

102   channels dissecting vegetated salt marshes and mangrove swamps (Finotello, Ghinassi, et al., 2020;

103   Horstman et al., 2021). In contrast, field studies on tidal meanders wandering through unvegetated

104   intertidal mudflats are still scarce (Choi et al., 2013; Kleinhans et al., 2009), and flow velocity

105   measurements are virtually nonexistent to date. This is a critical knowledge gap because significant

106   differences might exist in terms of flow fields between tidal channels wandering through vegetated

107   and unvegetated intertidal plains, especially concerning overbank stages (i.e., water levels that

108   exceed the channel bankfull capacity). Overbank velocities in vegetated settings dominated by

109   turbulence and friction are typically a magnitude lower than those observed on unvegetated

110   mudflats (Bouma et al., 2005; Christiansen et al., 2000; D'Alpaos et al., 2021; Friedrichs, 2011;

111   Hughes, 2012; Rinaldo et al., 1999a; Sullivan et al., 2015). Besides, overbank stages are more

112   frequent in mudflats than in salt marshes, owing to the relatively lower position occupied by

113   mudflat channel banks within the intertidal frame. As such, stage-velocity relations in mudflat tidal

114   channels can differ greatly from those observed in vegetated marshes and mangrove forests, and

115   overbank stages might have stronger control on tidal channel morphodynamics (D'Alpaos et al.,

116   2021; Hughes, 2012; Kearney et al., 2017; McLachlan et al., 2020; Sgarabotto et al., 2021),

117   potentially justifying the observed morphological differences of tidal channel networks in distinct

118   vegetational settings (Geng et al., 2021; Kearney & Fagherazzi, 2016; Schwarz et al., 2022; Wang

119   et al., 1999a, 1999b). These differences in landforming hydrodynamic processes are also likely to

120   affect the development of curvature-induced helical flow that is typically related to the

121   development and growth of meander bends in both rivers and salt-marsh tidal channels (Azpiroz-

122   Zabala et al., 2017; Finotello, Ghinassi, et al., 2020; Keevil et al., 2015; Kranenburg et al., 2019;

123   Nidzieko et al., 2009; Thorne et al., 1985). Such helical flow forms as a consequence of secondary

124   (i.e., cross-sectional) circulations, oriented toward the inner and outer bank in the near-bed and

125   near-surface zone, respectively, which result from the imbalance between the upward-increasing

126   centrifugal forces and the lateral pressure gradients created by the curvature-induced

127   superelevation of the water surface at the outer bank (Engelund, 1974; Prandtl, 1926; Rozovskiĭ,

128    1957; Solari et al., 2002). The downstream advection of secondary circulations operated by the

129    main streamwise flow produces a helical flow, as extensively documented in a variety of field

130    (Dietrich & Smith, 1983; Dinehart & Burau, 2005; Frothingham & Rhoads, 2003), laboratory

131    (Blanckaert, 2011; Liaghat et al., 2014), and numerical studies (Blanckaert & de Vriend, 2003;

132    Bridge & Jarvis, 1982; Ferguson et al., 2003).

133    Although secondary currents akin to those found in river meanders have been observed and

134    modelled in meandering salt-marsh creeks and large estuarine tidal channels (Finotello, Canestrelli,

135    et al., 2019; Finotello et al., 2022; Finotello, Ghinassi, et al., 2020; Kranenburg et al., 2019;

136    Nidzieko et al., 2009; Pein et al., 2018; Somsook et al., 2020; Somsook et al., 2022), their presence

137    in sinuous mudflat channels has yet to be demonstrated. In fact, previous studies (e.g., Choi, 2011;

138    Choi & Jo, 2015; Ghinassi et al., 2019; Kranenburg et al., 2019) suggested that the morphodynamic

139    processes governing meander evolution in intertidal mudflat settings can differ greatly from the

140    classic secondary-current-driven lateral channel migration mechanism acting in vegetated fluvial

141    and intertidal plains. For instance, Kleinhans et al. (2009) argued that owing to the higher

142    thresholds for erosion that characterize mudflat deposits, bank erosion is primarily due to bank

143    undercutting caused by backward-migrating steps along the channel bed driven by hydraulic jumps

144    that form during ebb tides. They also demonstrated that bank migration occurs preferentially in

145    very sharp bends, where flow separates from the meander inner (convex) bank and impinges

146    directly against the outer (concave) bank. Choi (2011) noted enhanced tidal channel migration in

147    association with episodic and seasonal increase of discharge due to, for example, heavy

148    precipitations, pointing to a strong control of these non-tidal processes on the morphodynamic and

149    sedimentology of tidal mudflat meanders. Accordingly, Choi and Jo (2015) measured pronounced

150    meander migration in the Yeochari macrotidal flat (South Korea) during the summer rainy season,

151    when point bars were observed to migrate as fast as 40 m per month due to increased runoff

152    discharge caused by heavy rainfalls in the order of tens to hundreds of millimeters per hour,

153    possibly compounded by monsoon precipitations. Finally, Ghinassi et al. (2019) suggested that

154    wave winnowing of mudflats during high-tides modulates meander morphosedimentary evolution,

155    leading to widespread bank collapses within the channel.

156    In view of the above, the structure of tidal flow fields in mudflat tidal meanders appears to be

157    worth investigating. Here we present novel hydroacoustic data from a meandering tidal channel

158    dissecting a macrotidal mudflat located along the Jiangsu coast (China). The aim of the study is

159    threefold, as we intend to: (i) highlight the characteristics of tidal flows within a meander bend

160    developed in an unvegetated tidal mudflat; (ii) unravel possible differences in meander

161    hydrodynamics among below-bankfull and above-bankfull (i.e., overbank) water stages; and (iii)

162    disclose the characteristics of secondary circulations and their relations with the overbank flows.

163    To the best of our knowledge, this study represents the very first attempt to directly measure tidal

164    flows in meandering mudflat channels.

165

## 2 Geomorphological setting and study-case

167    Our study case is found in the Yangkou tidal flat (YTF), an extensive mudflat system located on

168    the southern Jiangsu coast, northward of the Yangtze River Delta, which is bordered by the Yellow

169    Sea to the East and North and by the East China Sea to the South (Figure 2a). The YTF was formed

170    by abundant sediment supply input from both the Yangtze River and the Yellow River, which

171    historically allowed for seaward expansion of the whole Jiangsu province coastline (Shi et al.,

172    2016; Wang & Zhu, 1990). Sediments consist mainly of silty-muddy material, with average grain

173    sizes ranging between 10 and 45 μm (i.e., 4.5 ~ 6.6 φ) (Shi et al., 2016; Wang & Ke, 1997). In the

174    last 2 centuries, however, the seaward extent of the YTF has decreased from 5 ~ 11 km to about 5

175    ~ 8 km as a consequence of changes in sediment transport regime driven by anthropogenic

176    interventions, the latter including the diversion of the Yellow River to the Bohai Sea in 1855 (Ren

177    & Shi, 1986), and the construction of the Three Gorges Dam in 2003, which significantly decreased

178    sediment supply from the Yangtze River (Yang et al., 2014). In addition to this, land reclamation

179    projects, the building of oceanic outfalls, aquaculture, and the construction of wind farms have

180    further contributed to increasing anthropogenic pressures in the YTF area (Xu et al., 2019; Zhao

181    et al., 2020; Zhao & Gao, 2015). Nowadays, the whole intertidal area in the YTF covers

182    approximately 100 km$^2$, extending seaward from the shoreline with gentle slopes ranging between

183    0.5‰ and 1.2‰ on average (Wang & Ke, 1997; Zhu et al., 1986).

184    Intertidal mudflats in the YTF are dissected by extensive networks of tidal channels. These

185    channels serve as the main conduits for the propagation of both the East China Sea progressive

186    tidal wave and the southern Yellow Sea rotary tidal wave, which converge nearby the town of

187 Yangkou giving rise to complex coastal circulations (Liu et al., 1989). The tidal regime in the

188 study area is semidiurnal macro-tidal, with average and spring tidal ranges equal to 4.6 m and 8 m,

189 respectively. Morphodynamic processes are also affected by the East Asian Monsoon, which

190 blows with a mean winter wind speed of 4.2 m/s toward the southeast and a mean summer wind

191 speed of 2.8 m/s toward the northwest, respectively (maximum measured wind speed is 34 m/s;

192 (Li et al., 2011; Xing et al., 2012). As wave conditions in this region are mainly related to wind

193 speeds, wave heights are smaller in the summer and larger in the winter, with annual average

194 values ranging between 0.5 and 1.5 m (Chen, 2016). The annual precipitation is about 900 ~ 1000

195 mm on average, with the summer season accounting for more than 40% of the whole yearly rainfall

196 (Wang & Ke, 1997; Xing et al., 2012).

197 Our study site is a blind tidal channel found within a natural reserve facing the Xiaoyaokou Scenic

198 and the Xinchuan port, both located nearby the city of Yangkou (Figure 2b). The studied channel

199 is 1.9 km long and is characterized by average width of 8 m. With an overall channel sinuosity

200 equal to 1.5, it represents a well-developed meandering reach. The channel originates from a

201 fringing salt marsh, which borders the Xiaoyangkou Scenic and is covered by *Spartina alterniflora*

202 *Loisel* (Figure 2c,e), and extends seaward wandering through an unvegetated intertidal mudflat.

203 Freshwater fluxes from the Beiling river to the North and the Bencha canal to the South do not

204 interfere with the hydrodynamic regime of the studied channel, which is always submerged at high

205 tide and drains out almost completely at low tide.

206 In this study, we focused specifically on a meander bend located in the central portion of the

207 channel and surrounded by unvegetated tidal flats (Figure 2c,d,f). The studied bend is

208 characterized by a cartesian wavelength (i.e., the linear distance between bend inflections) $L_{xy}$=37

209 m, whereas the along-channel bend length ($L_s$) is equal to 56 m. Hence, the bend attains a sinuosity

210 $\chi=L_s/L_{xy}$=1.5. The average meander radius of curvature is $R$=19 m, and the amplitude, measured

211 as the maximum distance from the line passing through both bend inflections, is equal to $A$=18 m.

212 The cross-sectional width ($W$) decreases from 8.8 m to 8.3 m in the landward direction (average

213 width $\overline{W}$=8.5 m). Being the bankfull depth ($Y_B$) equal 1.20 m on average, the studied bend is

214 characterized by an average width-to-depth ratio ($\beta = \overline{W}/Y_B$) of about 7.1. All these

215 morphometric parameters are in line with typical values observed for tidal channels worldwide

216 (D'Alpaos et al., 2005; Finotello, D'Alpaos, et al., 2020; Hughes, 2012). While many regularly-

217   spaced small erosional gullies cut through the channel banks (Figure 2f), a 4 m wide and 0.5 m

218   deep side tributary, meandering in planform, is found landward of the apex of the studied bend
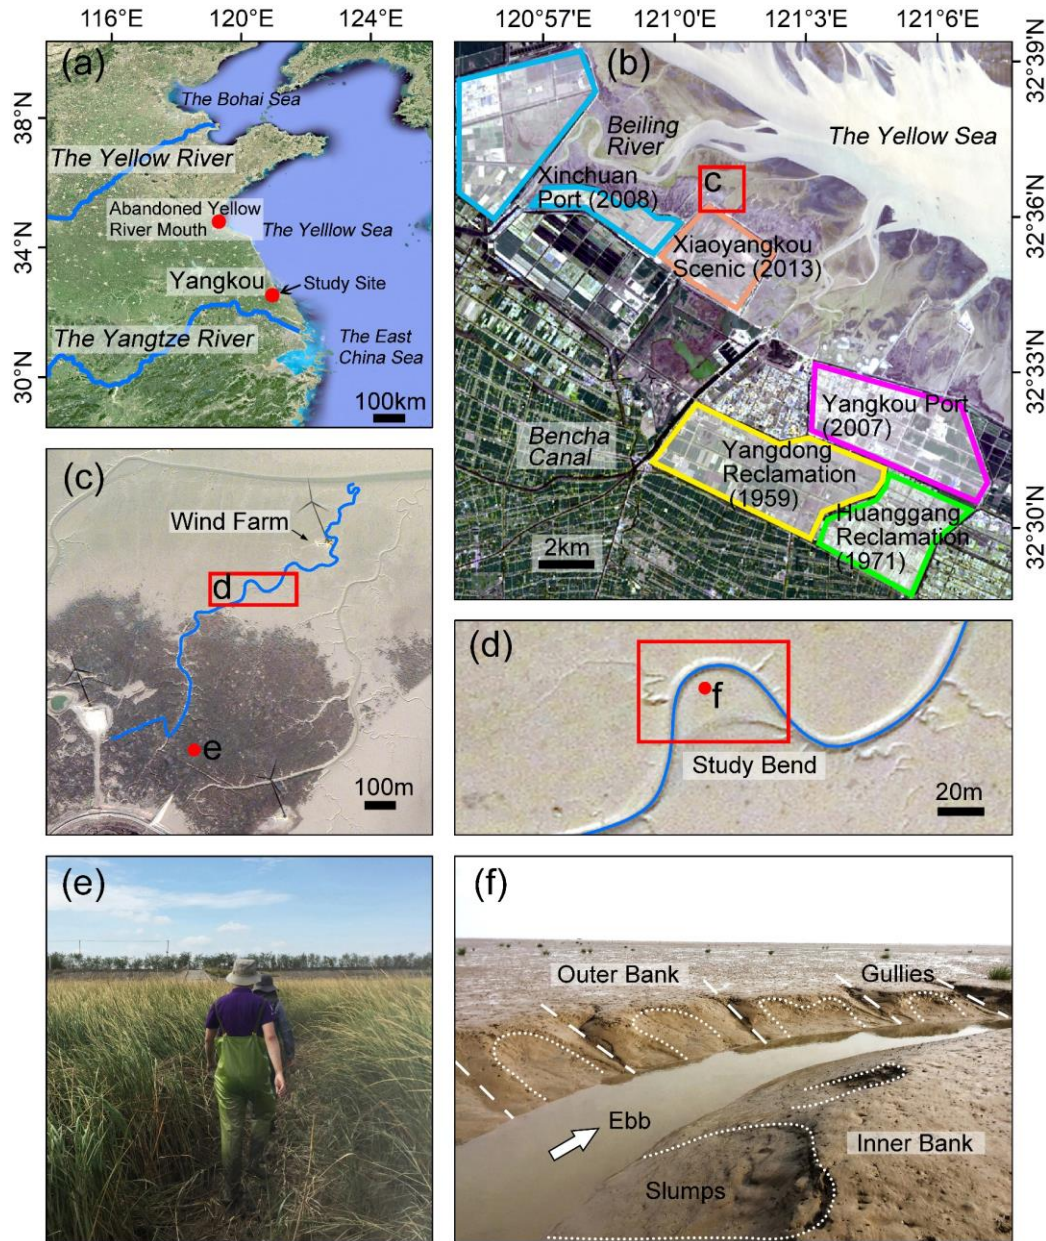

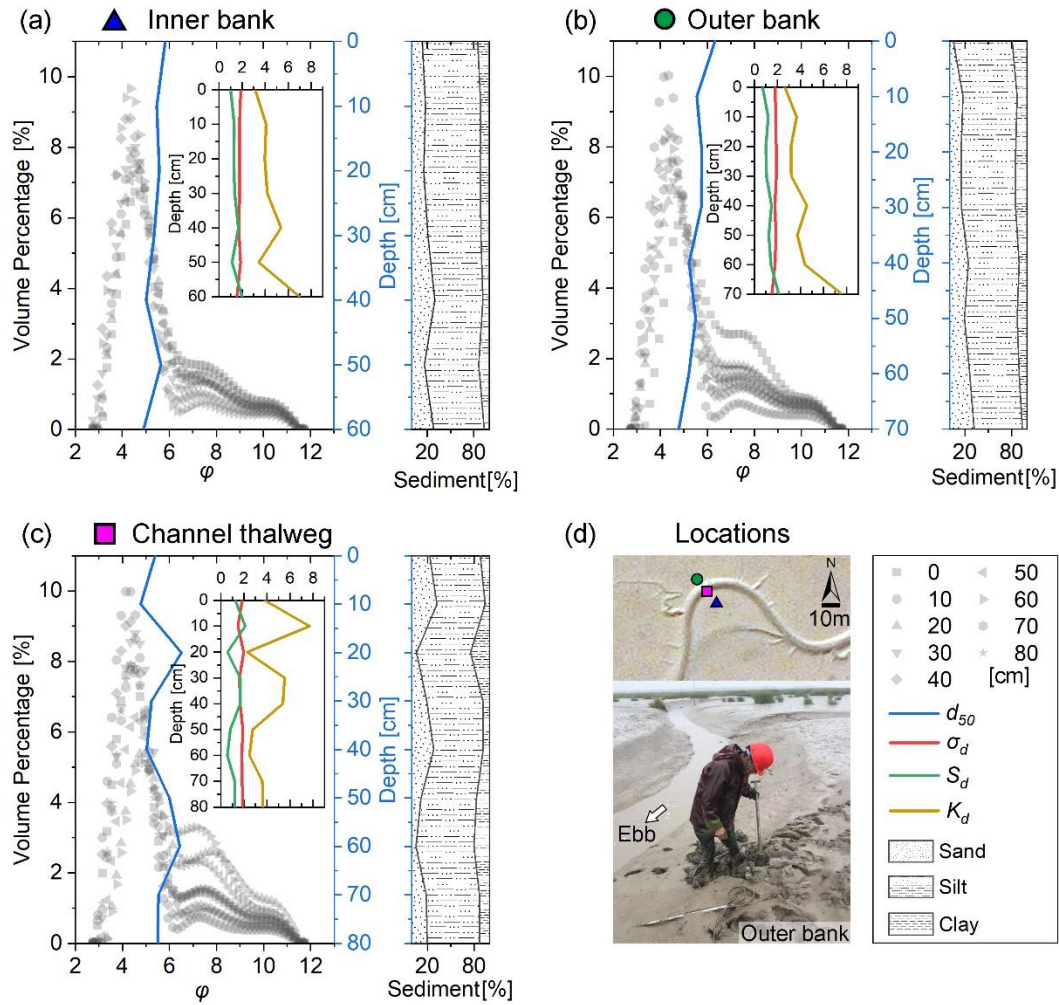

219   (Figure 2d).

220

221   Figure 2. Study site. (a) Overview of the study area. (b) The Yangkou tidal flat, Rudong County, Jiangsu Province,

222   China (Map data: Landsat8, OLI, April 9, 2021); areas affected by land reclamation activities are highlighted with

223   colored lines. (c, d) Overview of the meandering tidal channel investigated in this study, with a close-up view of the

224   analyzed meander bend (Map data: Google, TerraMetrics). (e) A photo showing vegetation features in the landward

225   portion of the channel, characterized by the widespread presence of *Spartina alterniflora Loisel*. (f) A photo of the

226   studied bend at low tide.

227

228

Figure 3. Sediment grain size distribution at the study site. Results of grain size analysis carried out on sediment cores collected at the study-bend inner bank (a), outer bank (b), and channel thalweg (c). Different symbols of gray-shaded data points denote different coring depths, as shown by the inset in the lower-right corner. Detailed coring locations are shown in panel (d), together with a seaward-looking photo of the coring operation at the outer bank. Sediment coring was carried out on the last day of fieldwork to avoid damaging the channel morphology before flow measurements.

235

In order to investigate sediment properties at the study site, we collected sediment cores at the meander inner bank, outer bank, and channel thalweg using a custom hand corer (coring depth ranging between 60 and 80 cm). Grain-size analysis was carried out at 10 cm intervals from the core top using a Mastersizer 2000 laser granulometer with a measuring range of 0.02 ~ 2000 μm

240    and a reproducibility error of $< 3\%$. Grain-size parameters - including median size ($d_{50}$), standard

241    deviation ($\sigma_d$), skewness ($S_d$), and kurtosis ($K_d$) - were calculated using the Moment Methods

242    (Friedman, 1962). Consistently with sedimentary characteristics of the whole YTF system,

243    sediments were found to be mostly cohesive, with clay volume content accounting for nearly 20%

244    (Figure 3). The median grain size is always smaller than 62.5 μm (i.e., 4φ). No significant grain-

245    size trends are observed from the core collected at the channel thalweg (Figure 3c), whereas fining

246    upward trends are found both at the inner and outer bank (Figure 3a,b).

247

## 3 Methods

### 3.1 Acoustic measurements of flow velocities

250    We continuously monitored water levels and flow velocities in the study meander bend from

251    October 14, 2020 to October 21, 2020. Three Nortek's new Acoustic Doppler Current Profiler

252    (AD2CP, Signature 1000kHz) were placed at three different sites along the studied bend, namely

253    the bend apex and both the landward and seaward inflections, whereas one Teledyne RDI

254    ADCP1200kHz was deployed at the confluence with the small side tributary (Figure 4a). All

255    instruments were placed at the channel thalweg with an up-looking orientation to record velocities

256    and pressures (Figure 4c,d,e,f). The fifth probe of Nortek AD2CPs can observe the vertical velocity

257    separately from the other four probes, thus effectively avoiding acoustic cross-interference so that

258    the noise in the vertical velocity signal is significantly lower than that of traditional ADCP

259    instruments. The three AD2CPs were programmed to operate at 1.0 Hz, recording velocities in 20

260    cm vertical bins over timespans at 5-minute intervals. The blanking distance of the AD2CP was

261    set to 10 cm, so that the center of the first sampling bin is 20 cm above the instrument. In contrast,

262    the Teledyne ADCP was programmed to operate at 1.0 Hz to record velocities in 5 cm bins at 5

263    minutes. The blank distance of the ADCP was set to 20 cm, so that the center of the first bin is

264    22.5 cm above the instrument. Details regarding the instruments' parameters are shown in Table
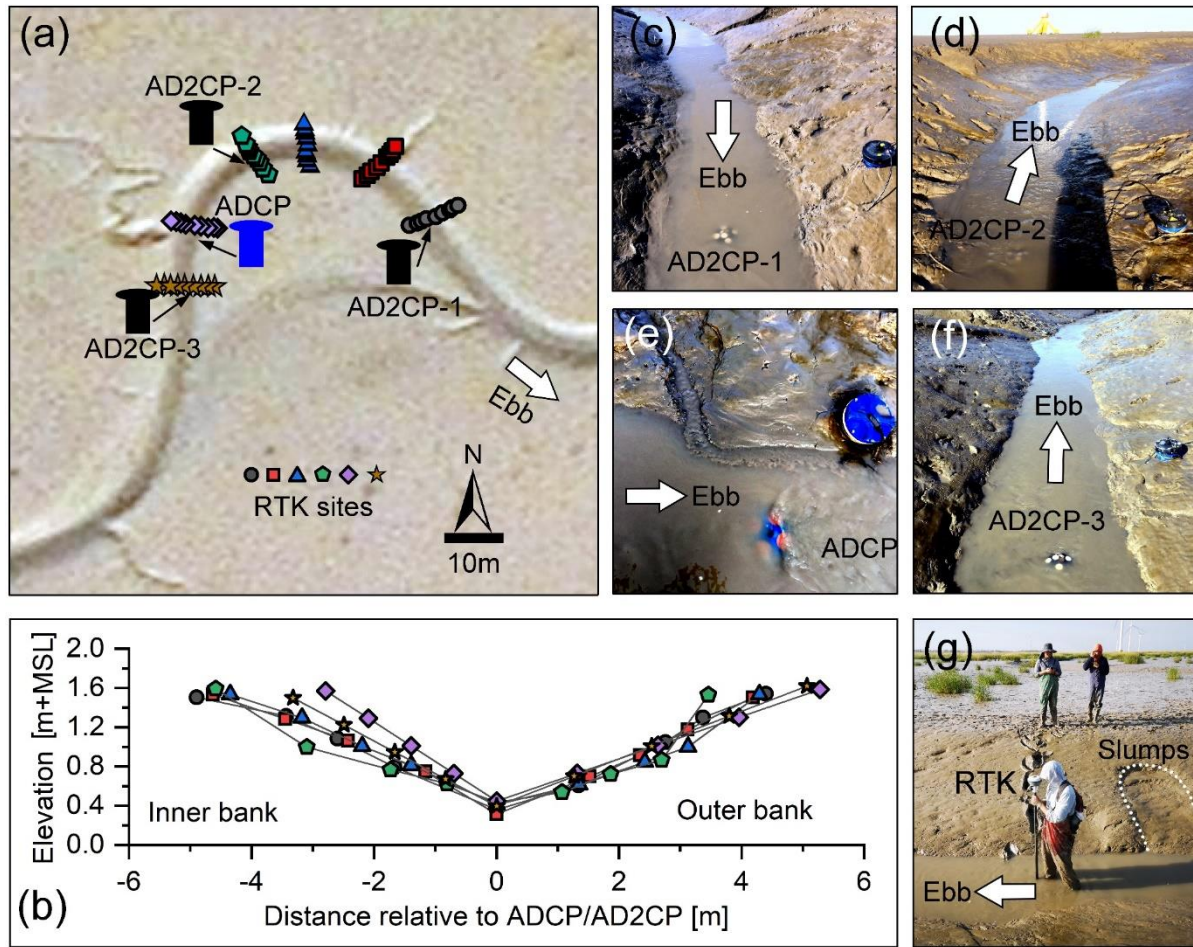

265    1.

Figure 4. Field measurements of flow fields and channel geometry. (a) Deployment locations of the AD2CPs (in black) and ADCP (in blue) instruments used in this study are shown together with the channel cross-sections where topographic surveys were carried out by means of an RTK-GPS. (b) Cross-sectional profiles of the surveyed channel cross-sections as obtained from the RTK data. Elevations are reported in meters above the mean sea level (MSL). Different symbols and colors denote different cross-sections according to the legend shown in panel "a". (c,d,e,f) Photograph of the deployed instrument prior to data acquisition. Names of individual instruments recall those reported in panel "a". (g) Photo of the topographic survey campaign carried out by means of an RTK-GPS during low tide. All the photos reported in panels (c,d,e,f, and g) were taken during the late stages of ebb tides.

280          Table 1. Parameters of the AD2CP and ADCP instruments used in this study

281

### 3.2 Data processing

Velocity data retrieved from the AD2CPs were converted into ENU system (i.e., $v_E$, $v_N$, $v_U$ for East-, North-, and Up-ward velocity, respectively), whereas ADCP data were already recorded in ENU format. Raw ENU data were then imported to Matlab (version 2019b) for initial quality control to remove noise generated by the interference of water bubbles, large suspended particles, echo intensity, and other disturbance factors (Lan et al., 2019). The procedure used for quality control is a modified version of Guerra and Thomson (2017)'s algorithm. For the data acquired using AD2CPs, values of echo intensity ≥ 25 dB and correlation magnitude ≥ 30% are used as threshold limits for high-quality data; for the data acquired by ADCP, values of echo intensity ≥ 30 dB and correlation magnitude ≥ 50% are instead used as thresholds. Velocity data were then despiked using the Phase-Space Thresholding Method (Goring & Nikora, 2002) and eventually averaged over the time length of individual bursts (i.e., 5 minutes). Moreover, ADCP data were also averaged vertically over 4 successive bins to allow for a more direct comparison with the AD2CP data. Overall, a total of 21 bins of velocity data were obtained for each instrument. For each bin, the horizontal velocity $\vec{v}$ was calculated as the vector sum of the eastward ($\overrightarrow{v_E}$) and northward ($\overrightarrow{v_N}$) velocity components (see Figure 5a) whereas depth-averaged velocities (*DAVs*) were computed for each measuring station as the average value of the whole $\vec{v}$ profile. Measured

299    values of upward velocities ($\overrightarrow{v_U}$) were instead maintained unaltered. Water depth ($Y$) data were

300    also obtained from pressure sensors integrated within the instruments. Based on the surveyed

301    topographic profile of each cross-section (Figure 4b), we were able to identify the water depth $Y_B$

302    corresponding to bankfull conditions. This allowed us to differentiate velocity data recorded for

303    water levels higher and lower than the bankfull threshold (i.e., above- and below-bankfull water

304    stages). Stage-velocity diagrams were also obtained based on binary plots of water levels ($Y$) and

305    depth-averaged values of flow velocity ($DAVs$) at each monitoring station (Figure 6 a-d). Both

306    $DAVs$ and $Y$ were also put in relation to the rates water-level change $\dot{Y} = dY/dt$ (Figure 6 e-p).

307     Tidal asymmetries were investigated based on two distinct metrics, concerning the asymmetry in

308    flood vs. ebb peak tidal velocities and flood vs. ebb durations, respectively (Figure 5 e-g). Since

309    the flow velocity is a function of the water depth, the peak tidal velocity index ($\rho_v$), which is the

310    ratio between the flood and ebb peak of $|\vec{v}|$ (Friedrichs & Aubrey, 1988; Guo et al., 2019), was

311    calculated at different water depths (i.e., at different positions along the water column) at 20 cm

312    intervals. To further differentiate between flow dynamics within the channel and outside of it,

313    distinct calculations of $\rho_v$ were performed averaging results by considering only velocity values

314    measured at water depths ($Y$) smaller and larger than the bankfull depth ($Y_B$), respectively (Figure

315    5e,f). In contrast, asymmetries in tidal duration ($\rho_d$) were computed as the ratio between the

316    duration of the falling and rising limb of the tidal wave (Friedrichs & Aubrey, 1988; Guo et al.,

317    2019). Both $\rho_d$ and $\rho_v$ provide a straightforward tool to differentiating flood-dominated ($\rho>1$) and

318    ebb-dominated ($\rho<1$) tidal flows.

319    To simplify the interpretation of velocity-data time series and filter out outliers, data were phase

320    averaged and subdivided into two distinct groups based on the values of the high-tide water depth

321    ($Y_H$) observed during each individual tidal cycle. Specifically, tidal cycles for which $Y_H>3.7$ m (i.e.,

322    the sixth to thirteenth tidal cycle in Figure 5) were classified as "high-amplitude tides" ($HAT$),

323    whereas all the other tidal cycles were considered "low amplitude tides" ($LAT$) (Tu et al., 2019;

324    Voulgaris & Meyers, 2004; Wang et al., 2013). For each tidal cycle, the instant corresponding to

325    $Y_H$ was assigned the time value of $t=0$. Then, data collected six hours before and after $Y_H$ were

326    ensemble-averaged at five-minute intervals (Figure 7a,b)

327    Finally, in order to better investigate flow structures and unravel possible secondary (i.e., cross-

328    sectional) circulations, velocity data were reprojected into two different components, namely, the

329    primary (i.e., streamwise) velocity $V_P$, corresponding to the main direction of in-channel tidal

330    flows, and the secondary (i.e., cross-sectional) velocity $V_S$, oriented orthogonally to $V_P$ (Bever &

331    MacWilliams, 2016; Finotello, Ghinassi, et al., 2020; Lane et al., 2000). In order to define the

332    directions of $V_P$ and $V_S$, previous studies have typically taken advantage of reprojection techniques

333    based on flow data recorded along the entire channel cross-section by ADCP instruments mounted

334    on moving vessels (Finotello, Ghinassi, et al., 2020; Lane et al., 2000; Parsons et al., 2013). These

335    techniques cannot however be applied to our data, since our instruments were operated in

336    stationary mode, and significant differences appear when observing flow velocities at above- and

337    below-bankfull stages. Thus, we assumed that the direction of $V_P$ corresponds to the direction of

338    the maximum horizontal velocity ($\overrightarrow{v_{max}}$) observed at the bottom vertical layer (i.e., $Y = 0.2$ m in

339    Figure 7c~f). Such a definition is based on the observation that the orientation of $\overrightarrow{v_{max}}$ at the

340    channel bottom is unequivocally defined and remains consistent during both the ebb and flood

341    phases (see Figure 4 and Figure 7c~f). Once $V_P$ is defined, the orientation of secondary velocity

342    ($V_S$) is immediately derived as the direction perpendicular to $V_P$. Details regarding the

343    determination of $V_P$ and $V_S$ at different measuring stations can be seen in Figure 8,9,10 and 11.

344    Close-up views of $V_S$ vectors for below-bankfull stages only are also shown in Supplementary

345    Figure S1.

346

## 4 Results

### 4.1 Flow magnitudes, tidal asymmetries, and stage-velocity relationships

349    Overbank flows invariably occurred for all the tide cycles on record. The high-tide water depth

350    ($Y_H$) reached a maximum value of 4.2 m on Oct. 18, whereas a minimum value of $Y_H$=2.2 m was

351    observed on Oct. 14. The latter was still higher than bankfull water depth ($Y_B$), which is about

352    $Y_B$=1.20 m (Figure 5a). There are no significant differences in horizontal velocity magnitudes ($|\vec{v}|$)

353    between the four monitoring stations, with peak velocities in the order of $|\vec{v}|$=0.96-0.99 m/s

354    consistently observed during the rising limb of the tide (Figure 5a,b,c,d). Pronounced differences

355    in flow velocity are observed for water stages above and below the bankfull depth. Specifically,

356    higher $|\vec{v}|$ values are typically observed for below-bankfull water stages, when tidal flows are

357    conveyed entirely within the channel, both during flood and ebb tides. In contrast, comparably

358    lower $|\vec{v}|$ values are found for water levels exceeding the bankfull depth $Y_B$, although relatively

359    large $|\vec{v}|$ values occur when the high-tide water depth ($Y_H$) exceeds a critical value of about 3.2 m,

360    that is, for tidal oscillations akin to spring-tide conditions (Figure 5a). When this happens, the

361    vertical velocity profiles display significant variations, with reduced (enhanced) velocities found

362    at water depths lower (higher) than $Y_B$.

363    The computed values of tidal flow asymmetries ($\rho_v$ and $\rho_d$) can be plotted as a function of the

364    high-tide water depth ($Y_H$) observed during each monitored tidal cycle (Figure 5e,f,g). Made

365    exception for the first monitored tidal cycle, flow velocities are found to be consistently flood-

366    dominated for below-bankfull depths ($Y<Y_B$, Figure 5e). In contrast, ebb dominance becomes more

367    common considering water depths above the bankfull ($Y>Y_B$), even though most of the data still

368    falls within the flood-dominated domain (Figure 5f). Changes in high-tide water depth ($Y_H$) seem

369    to not significantly affect peak flow asymmetry, although both data scattering and flood dominance

370    appear to decrease slightly as $Y_H$ increases, both for above- and below-bankfull water depths

371    (Figure 5e,f). Conversely, variations in $Y_H$ significantly affect tide duration asymmetry ($\rho_d$). The

372    collected data suggest the persistence of flood-dominated conditions in our study channel during

373    the entire monitoring period, with $\rho_d$ increasing proportionally to $Y_H$ in a statistically significant

374    fashion (Figure 5g).

375    Stage-velocity diagrams for all the measuring stations display pronounced variations in the

376    observed depth-averaged velocity (*DAV*), with *DAV* maxima typically occurring immediately

377    below the bankfull water depth both for flood and ebb tides (Figure 6a,b,c,d). Flood *DAVs* are

378    observed to decrease significantly once water depths exceed the bankfull stage. On the contrary,

379    ebb *DAVs* rapidly increase once water depths become lower than the bankfull water depth.

380    Although the peak *DAVs* are typically higher during the flood phase, which is in agreement with

381    our previous observations regarding flow asymmetries, ebb *DAVs* attain near-maximum values for

382    comparably longer times at water stages lower than bankfull (Figure 6a,b,c,d).

383    Similar to the *DAV* patterns, the rate of water-level change ($\dot{Y} = dY/dt$) peaks around the bankfull

384    stage during the flood, whereas ebb peaks of $\dot{Y}$ are observed for water stages well above the

385    bankfull (Figure 6e,f,g,h). Notably though, $\dot{Y}$ attains a nearly-constant value during most of the

386    ebb phase, whereas much more pronounced changes are observed during the flood. A statistically

387    significant, positive linear correlation is found between $\dot{Y}$ and *DAV* for below-bankfull stages

388    during both the ebb and the flood (Figure 6i,j,k,l), although such correlation is more robust for ebb

389    flows (Figure 6i,j,k,l). For overbank stages, significant correlations between $\dot{Y}$ and *DAV* can only

390    be obtained for the flood phase, whereas ebb *DAVs* are not significantly correlated to $\dot{Y}$ (Figure
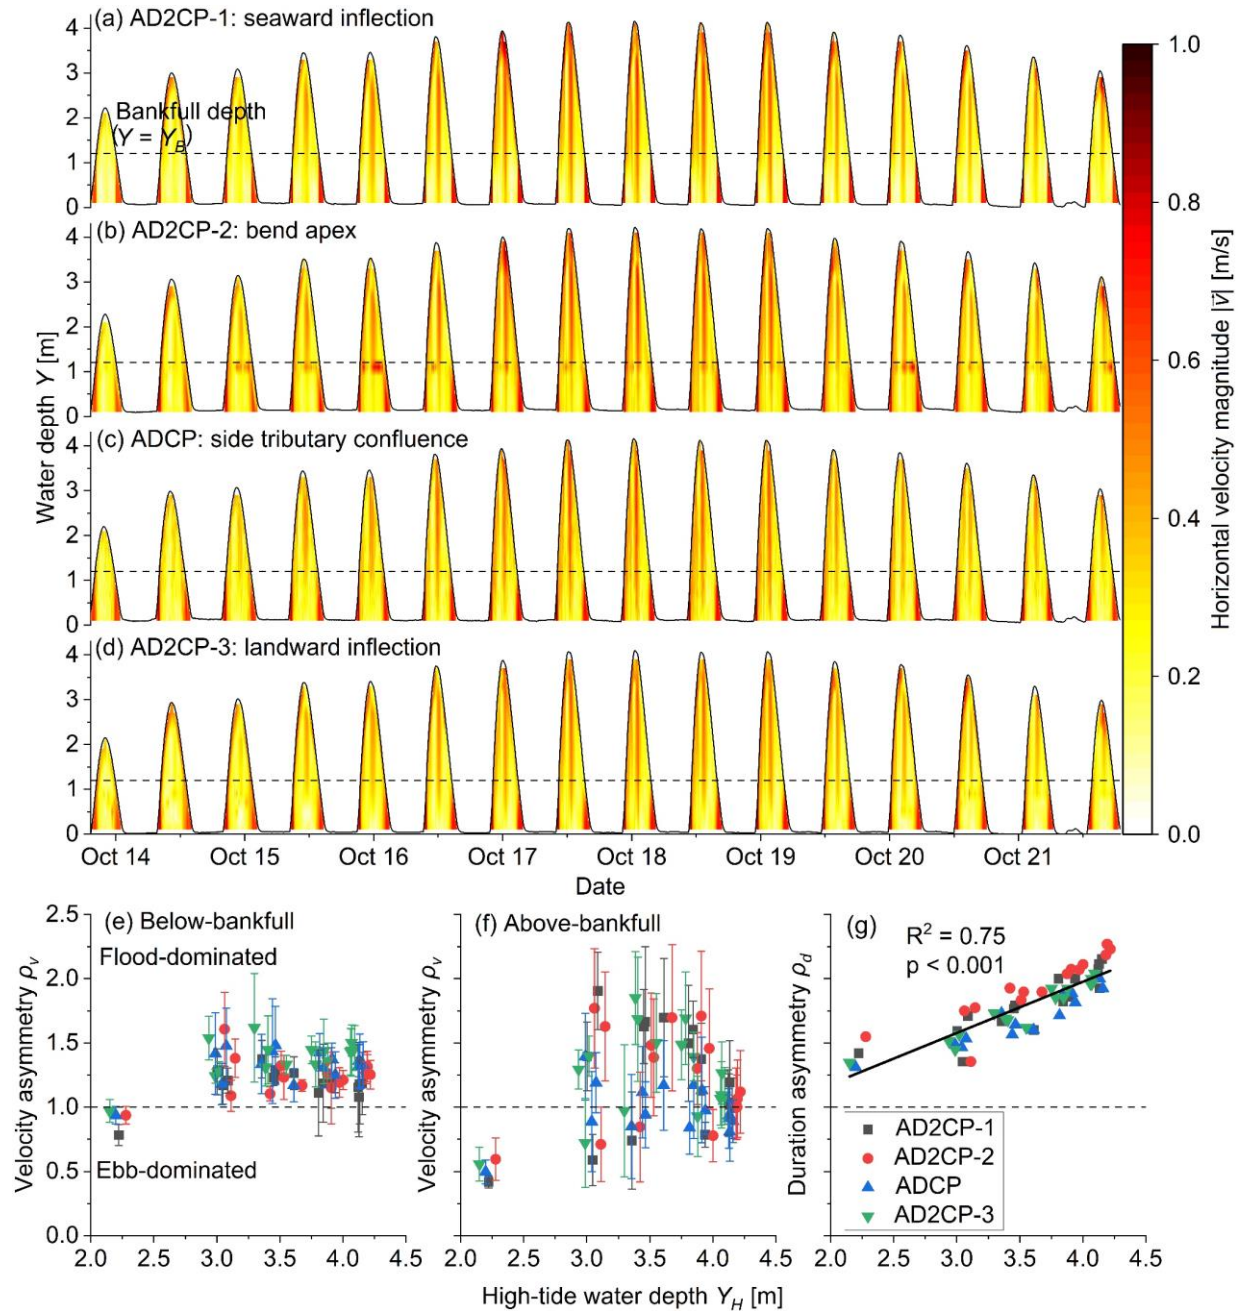

391    6m,n,o,p).

392

393

394     Figure 5. Time series of measured flow velocities and water depths. a,b,c,d) Time-continuous plots of horizontal

395     velocity magnitudes ($|\vec{v}|$) as a function of instantaneous water depth ($Y$) for AD2CP-1 (seaward inflection point,

396     panel a), AD2CP-2 (bend apex, panel b), ADCP (confluence with side tributary, panel c), and AD2CP-3 (landward

397     inflection point, panel d). The horizontal velocity magnitude is computed as $|\vec{v}| = \sqrt[2]{|\vec{v_E}|^2 + |\vec{v_N}|^2}$, where $\vec{v_E}$ and $\vec{v_N}$

398     are the Eastward and Northward velocity components measured by the acoustic instruments, respectively. The

399     horizontal, black-dashed line in each panel denotes water depth corresponding to the bankfull stage ($Y=Y_B$) for each

400     measuring station. (e,f) Values of peak tidal velocity asymmetry ($\rho_v$) at different measuring stations are plotted against

401     the high-tide water depth ($Y_H$) observed during each monitored tidal cycle. Panel e) shows $\rho_v$ for below-bankfull tidal

402     flows, whereas $\rho_v$ values for above-bankfull flows are displayed in panel f). Data points represent the average value

403     of $\rho_v$ computed at different depths, with error bars denoting standard deviation. (g) Values of tidal duration asymmetry

404     ($\rho_d$) at different measuring stations are plotted against the high-tide water depth ($Y_H$) observed during each monitored

405     tidal cycle. Different symbols and colors in panels e,f, and g denote different monitoring stations according to the

406     legend in the lower-right inset. Calculations of tidal asymmetries were carried out only when instruments were

407     submerged and both velocity and depth data could effectively be recorded.
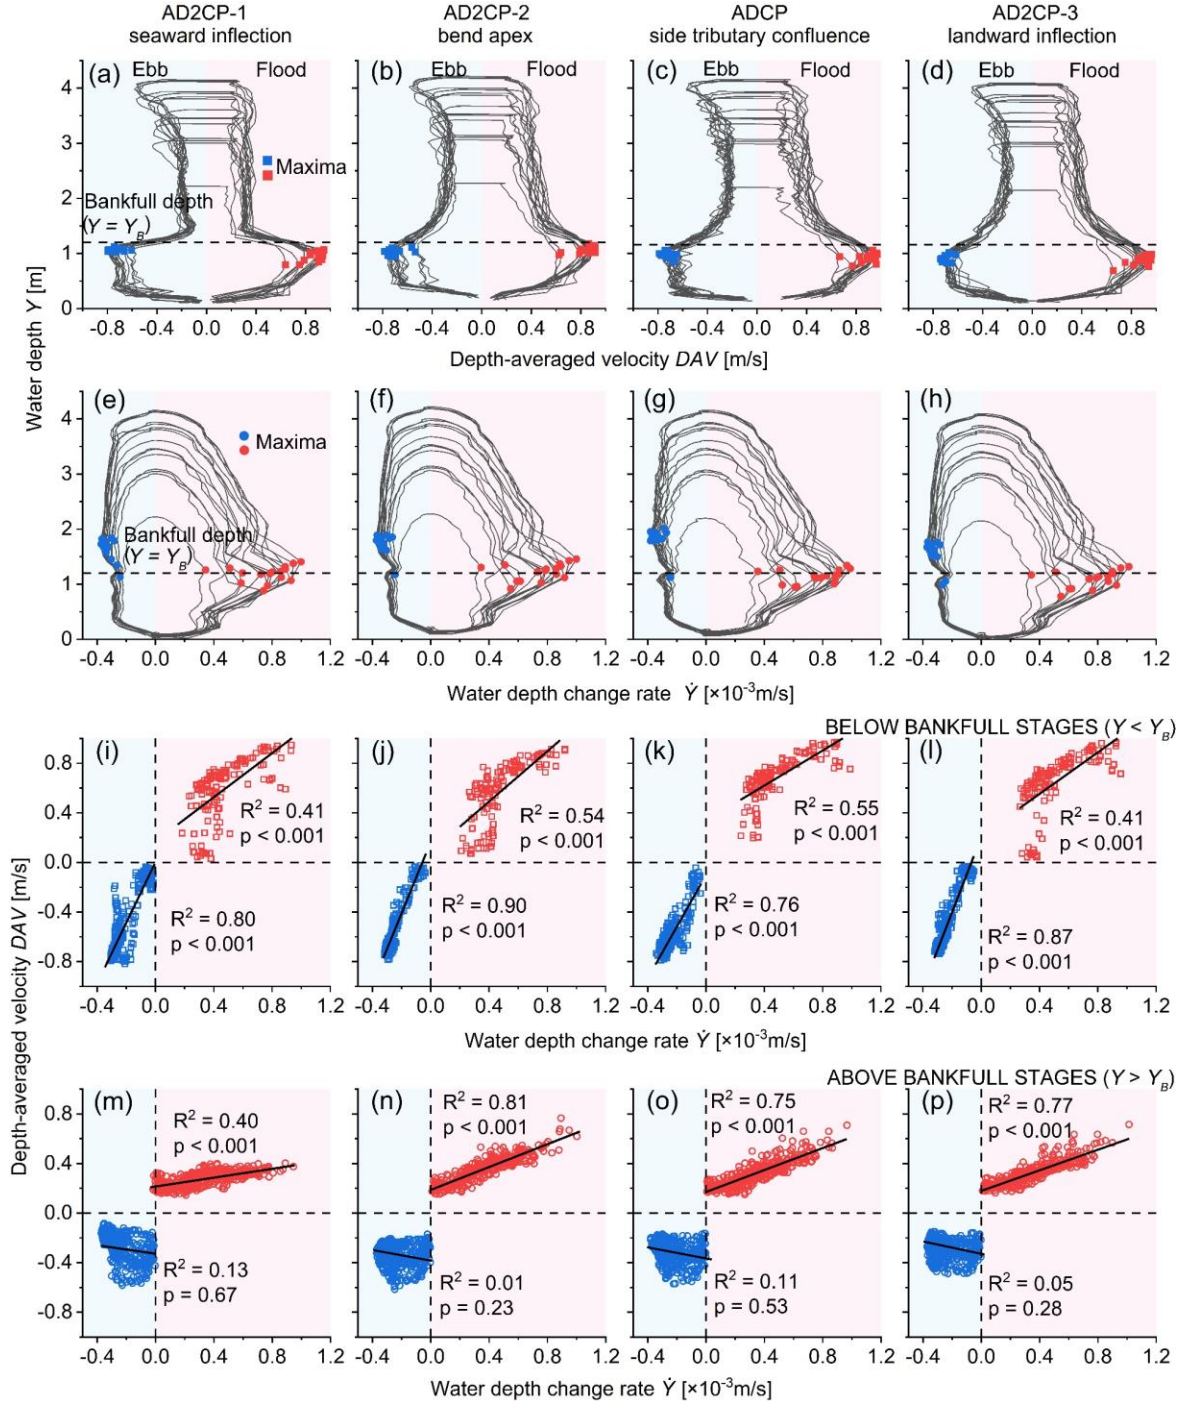

Figure 6. Relationships between depth-averaged velocity ($DAV$), water depth ($Y$), and water-depth change rate ($\dot{Y} = dY/dt$) at the four measuring stations. Columns from the left- to the right-hand side of the figure show, respectively, results for AD2CP-1 (seaward inflection point), AD2CP-2 (bend apex), ADCP (side tributary confluence), and AD2CP-3 (landward inflection point). Red and blue quadrants represent data obtained during the flood and the ebb phase, respectively. (a, b, c, d) Water depth ($Y$) vs. depth-averaged velocity ($DAV$) curves for all the monitored tidal cycles. Red and blue points denote the maximum flood and ebb $DAVs$ of each tidal cycle. (e, f, g, h) Water depth ($Y$)

415    vs. water-depth change rate ($\dot{Y}$) curves for all the monitored tidal cycles. Red and blue points denote the maximum

416    flood and ebb $\dot{Y}$ of each tidal cycle. (i, j, k, l) Depth-averaged velocity (*DAV*) as a function of water-depth change rate

417    ($\dot{Y}$) for below-bankfull stages during all the monitored tidal cycles. (m, n, o, p) Depth-averaged velocity (*DAV*) as a

418    function of water-depth change rate ($\dot{Y}$) for above-bankfull stages during all the monitored tidal cycles.

419

420        **4.2 Phase averaged velocities and secondary circulations**

421        *4.2.1 Horizontal flow velocities*

422    Horizontal flow vectors $\vec{v}$ at different depths are plotted for high-amplitude (*HAT*) and low-

423    amplitude (*LAT*) cycles separately (Figure 7c~f). At each measuring station, ebb and flood $\vec{v}$ for

424    below-bankfull stages are generally characterized by similar orientations, yet with opposite

425    directions, whereas more scattering is observed when flow depth exceeds the overbank stage.

426    Directions of overbank flows appear to be consistent across different measuring stations, with

427    flood and ebb flows directed to the southwest and southeast, respectively. In contrast, inter-site

428    variability of below-bankfull flows is more marked, as $\vec{v}$ appears to follow the orientation of the

429    channel axis, with $\vec{v}$ being more variable and generally less correlated to the channel axis

430    orientation for near-bankfull conditions (i.e., water depths $0.8 < Y < 1.2$m). It is also worthwhile

431    noting that flow directions at any given measuring station display little differences between *HAT*

432    and *LAT* cycles, both for water stages above and below the bankfull.

Figure 7. Ensemble phase-averaged horizontal velocity ($\vec{v}$) data at the four measuring stations. (a) Locations of measuring stations. (b) Time series of $\vec{v}$ magnitudes computed separately for high-amplitude tides (*HAT*) and low-amplitude tides (*LAT*) at each measuring station. (c,d,e,f). Vectors of horizontal velocities in *HAT* and *LAT* cycles plotted for different water depths (*Y*) at each measuring station during the ebb (blue) and flood (red).

438  *4.2.2 Streamwise velocities and secondary circulations*

439  In all the measuring sites, the primary (i.e., streamwise) velocity ($V_P$) reduces significantly once

440  the water stage reaches bankfull, both for *HAT* and *LAT* cycle. On the contrary, $V_S$ increases

441  significantly once water depth exceeds the bankfull (see panel b in Figures 8,9,10, and 11). To

442  better describe flow dynamics near the bankfull stage, we also plot $V_S$ vectors overimposed to $V_P$

443  magnitude values computed 15 minutes before and after the bankfull stage for both *HAT* and *LAT*

444  cycle (see panel c~f in Figures 8,9,10, and 11).

445  Velocity patterns observed at the seaward inflection site (AD2CP-1) are reported in Figure 8c~f.

446  During the flood, once the water depth exceeds the bankfull, $V_P$ decreases suddenly and even

447  reverses its direction in the upper layers, where $V_S$ increases significantly and takes direction

448  pointing toward the meander inner bank. In contrast, during the ebb, $V_S$ is very weak both for the

449  above- and below-bankfull stages (Figure 8c~f).

450  Similar results are observed at the landward inflection site (Figure 9). Particularly, peaks in $V_P$ are

451  observed for $Y<Y_B$, whereas the largest values of $V_S$ are attained when water depths exceed the

452  bankfull ($Y>Y_B$). During the flood, secondary velocities ($V_S$) are generally higher than at the

453  seaward inflection and consistently point to the outer bank in the upper vertical layers. Possible

454  secondary circulations emerge during the flood for both *HAT* and *LAT* cycles, with $V_S$ directed

455  toward the outer bank at the water surface and near the inner bank at the channel bottom. Overall,

456  data from both the landward and seaward inflection sites suggest the presence of secondary

457  circulations for overbank stages both for *HAT* and *LAT* cycles, with less obvious patterns being

458  observed during below-bankfull stages (Figure 8,9; see also Supplementary Figure S1a,b).

459  Secondary circulations can be observed at the bend apex (Figure 10), though they appear to be

460  generally weaker than those found at the bend inflections. During the flood, both $V_S$ magnitude

461  and secondary circulations are very weak when $Y<Y_B$ (Figure 10b~f and Figure S1c). Once

462  $Y$ reaches $Y_B$, $V_S$ increases and secondary circulations develop, especially during *HAT* cycles.

463  However, contrary to classic (i.e., fluvial) secondary circulation patterns where flows are directed

464  toward the outer bank in the uppermost portions of the water column, we observe secondary

465  circulations characterized by $V_S$ directed toward the inner bank near the water surface. During ebb

466  tides, $V_S$ are generally lower than during the flood, and secondary circulations are less clearly

467  noticeable both for *HAT* and *LAT* cycles.

468    Finally, at the confluence site, no significant secondary circulation is detected during either the

469    flood or the ebb, both for *HAT* and *LAT* cycles. During the flood, $V_S$ are consistently directed

470    toward the outer bank where the tributary is located and increase significantly when the water rises

471    above the bankfull stage (Figure 11b~f; see also Supplementary Figure S1d). In contrast, during

472    the ebb, a chaotic distribution of $V_S$ is found, with no clear indication of relevant secondary

473    circulations (Figure 11d,f, Figure S1d).
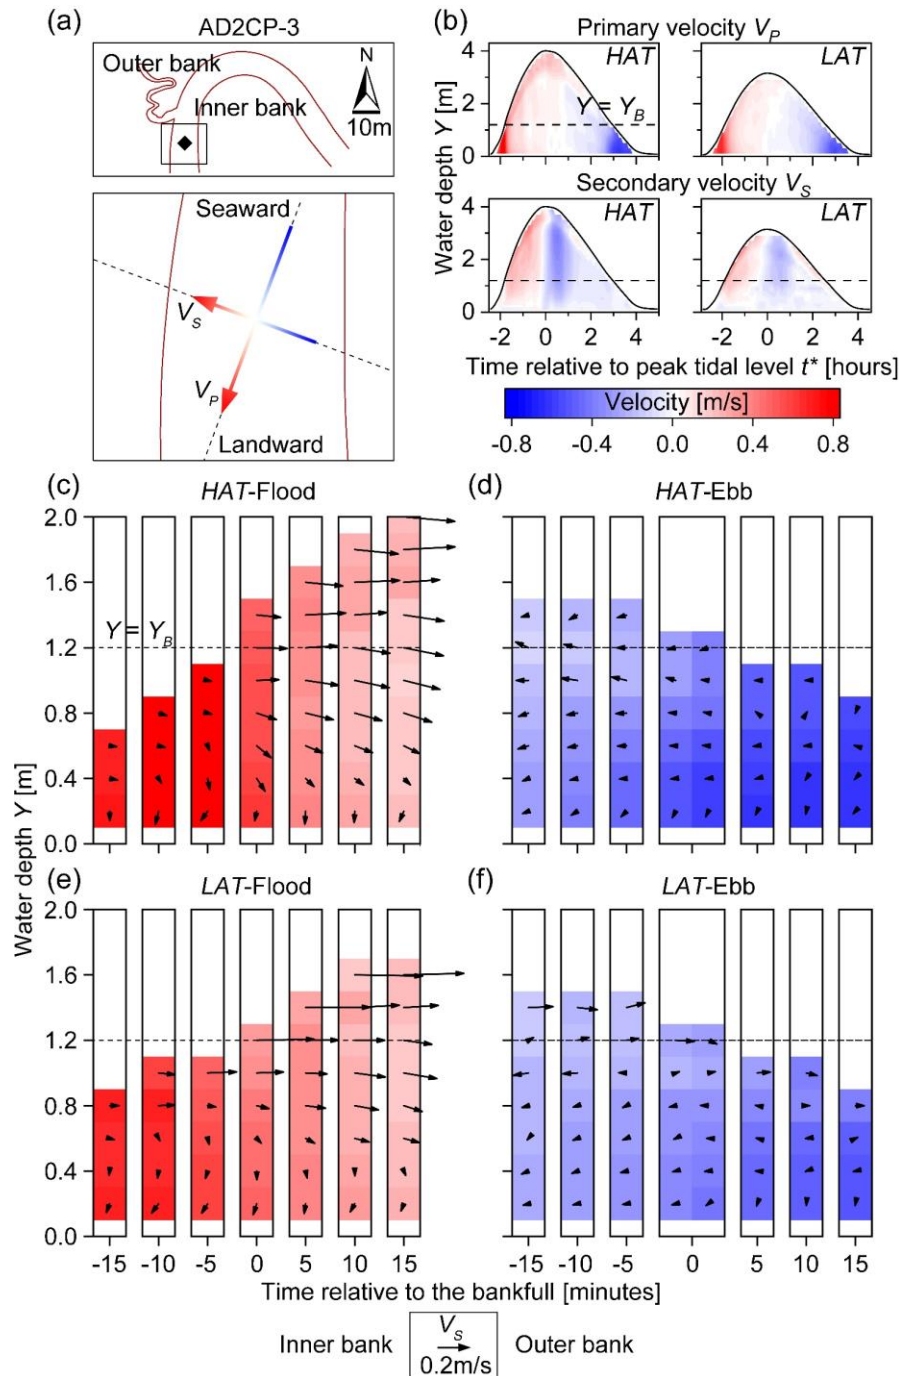

474

475

476    Figure 8. Flow decomposition at the seaward inflection site. (a) Location of AD2CP-1 and the direction of primary

477    ($V_P$) and secondary velocity ($V_S$). (b) Time series of $V_P$ and $V_S$ during high-amplitude tide (*HAT*) and Low-amplitude

478    tide (*LAT*). (c,d,e,f) Vertical distribution of $V_P$ magnitude with overimposed $V_S$ vectors computed, at 5-minute

479    intervals, 15 minutes before and after the bankfull stage in the *HAT* and *LAT* cycle. $V_s$ are directed toward the inner

480    and outer bank when pointing to the left- and right-hand sides of the figure, respectively.

501

502   **5 Discussions**

503       **5.1 Overbank flows and stage-velocity relationships**

504   Horizontal velocity distributions and stage-velocity diagrams of our studied channel display
505   critical differences compared to those observed in channels wandering through vegetated salt
506   marshes and mangrove forests (D'Alpaos et al., 2021; Fagherazzi et al., 2008; Hughes, 2012;
507   Kearney et al., 2017; McLachlan et al., 2020; van Maanen et al., 2015; see Figures 5 and 6). Owing
508   to the characteristic geomorphic structure of vegetated intertidal plains, peaks of ebb and flood
509   velocities in tidal channels typically occur just below or above the bankfull stage (i.e., for $Y>Y_B$),
510   with velocities being significantly reduced at $Y<Y_B$ and approaching null values when $Y$ is
511   minimum (see Bayliss-Smith et al., 1979; Boon, 1975; Fagherazzi et al., 2008; Hughes, 2012;
512   Kearney et al., 2017). In contrast, our monitored mudflat channel is characterized by sustained
513   velocities at $Y<Y_B$, with both horizontal ($\vec{v}$) and depth-averaged velocities ($DAVs$) peaks occurring
514   when tidal flows are confined within the channel banks (Figures 5 and 6). Notably, in all the
515   monitored sites velocities are relevant ($DAV \approx 0.8$ m/s) even for reduced water depth ($Y<0.5$ m),
516   especially during the ebb (see Figure 6a,b,c,d). Overbank stages are instead characterized by
517   reduced velocities, both in terms of $\vec{v}$ and $DAV$ values (Figures 5 and 6).

518   These discrepancies in velocities fields between channels found in vegetated and unvegetated
519   intertidal settings are likely due to the relative speed at which tides can propagate within and
520   outside tidal channel networks. Specifically, frictionally-dominated tidal flows across vegetated
521   intertidal plains make channels preferential pathways for tide propagation even when water levels
522   exceed the bankfull (i.e., for $Y>Y_B$; D'Alpaos et al., 2007; Rinaldo et al., 1999a, 1999b). In contrast,
523   flow resistance in unvegetated mudflats is comparable between tidal channels and intertidal plains,
524   such that tide propagation through unvegetated intertidal mudflats is dominated by sheet flow.
525   This hypothesis is supported by field data from the meso-macrotidal Scheldt Estuary

526  (Vandenbruwaene et al., 2015) highlighting similar velocities within tidal channels (0.3~1 m/s)

527  and across bare intertidal mudflats (0.1~0.4 m/s), in contrast to salt marshes wherein tidal flow

528  velocities are typically lower than 0.1 m/s. In our studied channel, flow velocities for above- and

529  below-bankfull stages are found to be in the range 0.2~0.4 m/s and 0.2~1 m/s, respectively (Figure

530  5,6), which roughly correspond with the results of Vandenbruwaene et al. (2015). The latter data

531  also suggest that instantaneous water levels are not significantly different within channels and

532  across mudflats, in contrast to frictionally-dominated vegetated intertidal plains where significant

533  differences in instantaneous water levels occur moving away from tidal channels (D'Alpaos et al.,

534  2021; Rinaldo et al., 1999a, 1999b; Sullivan et al., 2015).

535  Besides differences in bottom friction at overbank stages, one should also appreciate that

536  hydrodynamic dissimilarities are to be expected in mudflat vs. salt-marsh channels as a

537  consequence of distinct characteristic elevations of both their banks and the adjoining intertidal

538  platforms. Mudflat channels typically occupy the lower portions of the intertidal frame, their bank

539  elevation typically ranging between the mean sea level (MSL) and the mean low water springs

540  (MLWS). This allows for significant water depths at above-bankfull stages, which reduce flow

541  confinement within the channel and limit channel flow velocities (Brooks et al., 2021). In contrast,

542  channel banks in salt marshes are typically located in the highest portions of the intertidal frame,

543  which ensures in-channel flow confinement and sustained flow velocities even for large tidal

544  oscillations, effectively limiting above-bankfull water depths. In our study case, high $\vec{v}$ during

545  overbank stages are only observed when peak tidal levels exceed $Y_{max}$>3.2 m, that is, for spring

546  tidal cycles (Figure 4a,b,c,d) or, more generally, for high-amplitude (*HAT*) tidal cycles (Figure 7b).

547  Such high $\vec{v}$ values are however likely related to overbank circulations occurring at the scale of

548  the entire mudflat systems, which are not necessarily related to flow dynamics within the channel.

549  This is confirmed by the analysis of $\vec{v}$ directions along the water column (Figure 7c), which

550  testifies clear deviations of tidal flows at $Y$>$Y_B$ relative to the orientation of the channel axis both

551  for *HAT* and *LAT* tidal cycles. Such a deviation produces consistent flow directions in all the

552  monitored sites, with tidal flows being directed to the South-East and South-West during ebb and

553  flood tides, respectively (Figure 7c).

554  These observations altogether support the idea that differences in the character of overbank flows

555  result in marked hydrodynamic dissimilarities between tidal channels dissecting vegetated and

556   unvegetated intertidal plains. Such differences are also likely to affect curvature-induced

557   secondary circulations and the related meander morphodynamic evolution, as we discuss in detail

558   in the next sections.

559

### 5.2 Secondary circulations and curvature-induced helical flows

561   According to classic flow fields observed in sinuous channels, secondary (i.e., cross-sectional)

562   circulations are observed in our study bend, both during high-amplitude (*HAT)* and low-amplitude

563   (*LAT*) tidal cycles (Figures 8,9,10,11). These secondary circulations are more pronounced during

564   overbank stages, their intensity increasing as the water depth increases within the studied channel.

565   Indeed, secondary circulations tend to be stronger for *HAT* than *LAT* cycles (Figures 8,9,10,11).

566   They also appear to be mostly related to flood flows, which is in agreement with the generally

567   flood-dominated character of tidal flows observed in the studied bend (Figure 5e,f,g). In some

568   cases, the orientation of secondary circulations is reversed compared to classic flow models such

569   as, for example, at the seaward bend inflection as well as at the meander apex (Figure 8 and Figure

570   10), where secondary circulations are directed toward the inner and outer bank at the top and

571   bottom of the water column, respectively. Secondary currents can trigger cross-sectional sediment

572   transport processes such that fine-grained deposits are transported up to the point bar from the

573   channel bed, giving rise to fining upward trends due to the progressive upbar weakening of

574   secondary currents (Bathurst et al., 1977; Blanckaert, 2011; Dietrich, 1987; Termini & Piraino,

575   2011). This is supported by the fining upward trends that are consistently observed from sediment

576   cores collected at different sites along the studied bend (Figure 3).

577   Interestingly, secondary circulations are more pronounced at the meander inflections than at the

578   apex, where they should be stronger owing to higher channel curvature. This could however

579   depend on the surveying strategy we used, since we only monitored the velocity profile in

580   correspondence to the channel axis rather than across the entire cross-section. Previous studies

581   have demonstrated that secondary circulation cells do not necessarily occupy the whole channel

582   cross-section (e.g., Blanckaert, 2009, 2011; Finotello, Ghinassi, et al., 2020). Particularly,

583   hydrodynamic nonlinearities can arise in sharp bends characterized by radius-to-width ratios

584   $R/\overline{W}$ lower than 2-3, and flow separation may occur either at the inner or outer bank, respectively,

585    immediately upstream or downstream of the bend apex (Blanckaert et al., 2013; Finotello, Ghinassi,

586    et al., 2020; Hickin, 1978; Hickin & Nanson, 1975; Hooke, 2013; Parsons et al., 2004; Rozovskiĭ,

587    1957). Flow separation, which is common in tidal meanders owing to the high curvature values

588    that they typically display (Ferguson et al., 2003; Finotello, D'Alpaos, et al., 2019), can effectively

589    reduce the portion of the channel that is hydrodynamically active and confine curvature-induced

590    secondary circulations to the nonrecirculating portion of the primary flow (Finotello, Ghinassi, et

591    al., 2020; Leeder & Bridges, 1975; Parsons et al., 2004). Our studied meander bend is characterized

592    by a $R/\overline{W}$=2.2, and the formation of flow sepeartion is therefore highly likely. Direct measurement

593    of tidal flows across the entire channel cross section would be necessary to settle the dispute, but

594    such data are hard to collect because channel banks at our studied site are flooded by more than 3

595    m of water at high tides, thus making field measuring campaigns complicated. Nevertheless, we

596    can still estimate the chance for flow separation at the apex of our studied channel by comparing

597    our data with the results obtained by Leeder and Bridges (1975) for intertidal meanders in the

598    vegetated Solway Firth (Scotland). According to Leeder and Bridges (1975), the chances for flow

599    separation in tidal meander bends can be expressed as a function of bend tightness ($R/W$) and

600    Froude number ($Fr$). Although extending the results of Leeder and Bridges (1975) to unvegetated

601    mudflats might not be entirely appropriate, results would still offer useful insights on the possible

602    occurrence of flow separation, especially for below-bankfull stages when tidal flows are confined

603    within the channel. Since our measurements include several consecutive tidal cycles, we were able

604    to calculate how the $R/W$ changes according to varying water depths. Specifically, we assumed

605    that $R$ does not vary significantly with changing water elevation, and we computed the channel

606    width $W_Y$ corresponding to different water depths ($Y$) based on topographic data of the meander-

607    apex cross-section (Figure 4b). Plotting of $R/W_Y$ against $Fr$ shows that flow separations at the

608    bend apex site are likely to occur at near-bankfull stages (Figure 12). This is clearly related to the

609    morphology of the studied bend, which is characterized by a relatively low width-to-depth ratio

610    ($\beta$), whereby $W_Y$ increases rapidly as $Y$ increases, thus producing progressively lower $R/W_Y$ in

611    the range from 8 to 2. In addition, flow velocities at the below-bankfull stage generate a modest

612    $Fr$ value of 0.2~0.3, which can possibly induce flow separations (Leeder & Bridges, 1975). In

613    contrast to our observations, Figure 12 suggests that flow separation will be suppressed at overbank

614    stages, likely because of the observed flow velocity reduction at $Y>Y_B$. Care should be however

615    given when extending the results proposed by Leeder and Bridges (1975) to situations where tidal

616   flows do not remain confined within channel banks. Regardless, our analyses support the idea that

617   reduce secondary circulations observed at the meander apex could be ascribed to flow separation,

618   which makes secondary circulations hard to identify through localized flow measurements.

619   Regardless of flow separation, it is worthwhile noting that secondary circulations are stronger

620   during overbank stages, when flow confinement within channel banks is significantly reduced and,

621   as a result, primary velocities ($V_P$) are small. Thus, there seems to be a phase shift between peaks

622   of primary ($V_P$) and secondary velocity ($V_S$), such that $V_P$ is maximum when $V_S$ is low, and vice

623   versa. Such a shift would effectively limit the advection of cross-stream circulations operated by

624   the primary flow, thus hampering the formation of characteristic curvature-induced helical flows

625   (e.g., Blanckaert, 2011; Blanckaert & de Vriend, 2003; Dinehart & Burau, 2005; Ferguson et al.,

626   2003; Frothingham & Rhoads, 2003). Moreover, we notice that primary velocities at overbank

627   stages are sometimes characterized by reverse direction relative to below-bankfull stages, that is,

628   $V_P$ are directed seaward (landward) during flood (ebb) tides (see for example Figure 8c). This

629   would further limit the transfer of secondary circulation by primary velocity along the meander

630   bend, thus hampering the formation of helical flows even further. Such behavior has not been

631   observed in tidal channels flanked by vegetated intertidal plain, wherein $V_P$ and $V_S$ maxima are

632   approximately in phase and correspond roughly to near-bankfull water stages (e.g., Fagherazzi et

633   al., 2008; Finotello, Ghinassi, et al., 2020; Kearney et al., 2017). Additionally, secondary

634   circulations also appear poorly developed at the confluence site. It is well known that complex

635   circulation patterns can arise at channel confluences (e.g., Lane et al., 2000; Leite Ribeiro et al.,

636   2012; Rhoads & Kenworthy, 1995; Schindfessel et al., 2015), which are likely to suppress

637   curvature-induced secondary flows. Nonetheless, one should appreciate that channel confluences

638   in intertidal mudflat channel networks are somehow less frequent than in networks carving

639   vegetated intertidal plains, owing to the lower drainage density that characterizes bare intertidal

640   areas (e.g., Kearney & Fagherazzi, 2016). Therefore, flow disturbances and helical flow disruption

641   due to channel confluences and bifurcations are not likely to have a significant limiting effect on

642   meander morphodynamics in intertidal mudflats.

643   Overall, the results we illustrated so far suggest poor development of curvature-induced secondary

644   flows in intertidal mudflat meander bends. The implications of this hydrodynamic peculiarity, as

645   well as those highlighted in Section 5.1, for the morphodynamics of intertidal mudflat meanders,

646   will be discussed in the next section.

647

648

649 Figure 12. Flow separation in tidal meander bends according to Leeder & Bridges (1975). The normalized radius of
650 curvature ($R/W_Y$) is plotted as a function of Froude number ($Fr$) for distinct tidal flow depth ($Y$) and velocity ($U$) at
651 the apex of the studied meander bend. The parameter $W_Y$ represents the effective bend width corresponding to different
652 water depths ($Y$), whereas $Fr$ is calculated for different water depths $Y$ and the corresponding uniform flow velocities
653 $U$, the latter being approximated by the depth-averaged velocity ($DAV$). Colors denote varying normalized water
654 depths, computed as the ratio between instantaneous water depths and the maximum water depth ($Y_{max}$) observed
655 during the entire monitoring timespan. Filled dots denote below-bankfull water stages ($Y<Y_B$, where $Y_B$ is the bankfull
656 depth), whereas empty squares highlight above-bankfull stages ($Y>Y_B$). Original data points from Leeder and Bridges
657 (1975) are also reported using gray markers, along with their empirical line separating bends with and without flow
658 separation.

659

660 **5.3 Implications for meander morphodynamics**

661 Since the generation and propagation of helical flow are hampered, questions arise regarding what
662 are the chief morphodynamic processes driving meander evolution in unvegetated intertidal
663 mudflats. Previous studies suggested that mudflat meanders can form and develop without
664 significant secondary circulations. For example, the evolution of small mudflat meandering
665 channels (about 1 m wide) in the Westerschelde estuary (Netherlands) was found to be primarily

666    driven by late-ebb flows, which determined the erosion of channel bed due to backward-migrating

667    steps generated by hydraulic jumps, which in turn promoted channel bank erosion due to bank

668    undercutting and pronounced flow separation in sharp bends (Kleinhans et al., 2009). In our

669    studied channel, sustained velocities at low water stages (Figures 5,6,8,9,10,11), together with

670    direct visual inspections of sustained flow velocities near the end of ebb tides (see Figure 4),

671    support the idea proposed by Kleinhans et al. (2009) that the morphodynamics of intertidal mudflat

672    meanders is strongly controlled by late-ebb flows rather than by classic bar-hugging helical flow

673    produced by curvature-induced secondary flows at high-water stages. Reduced control of helical

674    flows on channel morphodynamics is also testified by the symmetric, V-shaped form of the studied

675    channel cross-sections (Figure 4b), which attests to the scarce development of secondary (i.e.,

676    cross-sectional) flows and contrasts with the asymmetrical U-shaped cross-sections displayed by

677    meandering channels in vegetated tidal marshes (Finotello, Ghinassi, et al., 2020; Zhao et al.,

678    2022).

679    In contrast to late-ebb flows, we speculate that tidal flows at early-flood stages are not likely to

680    have significant effects in terms of bank undercutting and sediment transport because velocities

681    increase more slowly than during late ebb, and rates of water depth change through time ($\dot{Y}$),

682    though sustained, do not produce significant variations in $DAVs$ (Figure 6). Our analyses indeed

683    confirm that tidal flows tend to be ebb-dominated at low water depths (Figure 5e,f), and also

684    highlight that at $Y<Y_B$ ebb velocities attain values close to the maximum for much longer periods

685    than during the flood (Figure 6), thus likely enhancing the morphodynamic control of late-ebb

686    flows on channel evolution. Moreover, late-ebb flows are likely to occur even for tidal oscillations

687    lower than those we monitored here, whereas pronounced overbank flows and related secondary

688    circulations require significant tidal oscillations to be formed. Because intense late-ebb flows act

689    at every tidal cycle and operate for extended periods, the total morphodynamic work they produce

690    is in all likelihood much more significant than that produced during other tidal phases, further

691    supporting the hypothesis that late-ebb tidal stages are the most morphodynamically relevant for

692    mudflat meander evolution.

693    The above-described morphodynamic control of late-ebb stages is likely to be even more relevant

694    compared to vegetated tidal landscapes due to the absence of vegetation not only on intertidal

695    plains but also within tidal channels. In fact, previous studies focusing on salt-marsh channels

696   demonstrated how in-channel aquatic vegetation can enhance bottom roughness and flow
697   turbulence (e.g., Finotello, Ghinassi, et al., 2020; Folkard, 2005), further limiting tidal flow
698   velocities at low stages, especially in relatively small channels with widths comparable to the
699   characteristic size of vegetation patches. The presence of aquatic vegetation would clearly prevent
700   significant morphodynamic work to be performed by late-ebb tidal stages, which is likely not the
701   case in the unvegetated mudflat channel we investigated here.

702   In addition to the above, meander morphodynamics in unvegetated intertidal flats can also be
703   driven by episodic and seasonal increases in discharges due to heavy rainfalls and melting snows
704   (Choi et al., 2013; Choi & Jo, 2015). Choi (2011, 2014) observed that these episodic events are
705   likely to cause abrupt morphologic changes, pronounced point bar migration, frequent meander-
706   bend cutoff, as well as channel abandonments. Particularly, significant rainfall-induced runoff
707   during low tides would mimick late-ebb flows, thus further increasing the morphodynamic
708   relevance of seaward-directed, shallow, in-channel flows. New field measurements will however
709   be required to support this hypothesis in the Yangkou tidal flat, since the data presented in this
710   study were collected in October, which is outside the monsoon season.

711   Storm waves could also induce bank collapses in unvegetated tidal channels (Choi, 2011; Choi &
712   Jo, 2015; Ghinassi et al., 2019), thus critically affecting meander morpho-sedimentary evolution.
713   In spite of the absence of vegetation that can help stabilize banks and prevent erosion, no collapsed
714   slump blocks were observed within our study channel (Gabet, 1998; Hackney et al., 2015),
715   although such blocks could be easily disgregated and removed, once formed, by sustained in-
716   channel velocities combined with the absence of additional cohesion given by vegetation roots.

717   Bank collapses can also form due to significant tidal oscillations and pore-excess pressure between
718   channel and banks driven by rapid changes in water levels (Zhao et al., 2022; Zhao et al., 2019),
719   which generate significant seepage flows (e.g., Gardner & Wilson, 2006; Wilson & Morris, 2012).
720   Seepage flows during late-ebb tides, also favored by extensive bioturbation due to fiddler-crab and
721   mudskipper burrowing (Harvey et al., 2019; Ishimatsu et al., 1998; Perillo et al., 2005; Xin et al.,
722   2022), are likely responsible for the widespread bank slumps that we observed at the middle and
723   lower portions of channel cross-sections in the studied channel (Figure 13). Notably, strong
724   seepage flows can also help explain why sustained velocities are observed over nearly the entire

725 duration of the ebb phase (Figure 6 a,b,c,d), and further support the idea that the ebb-late phases

726 exert a strong control on the morphodynamics of intertidal mudflat meanders.

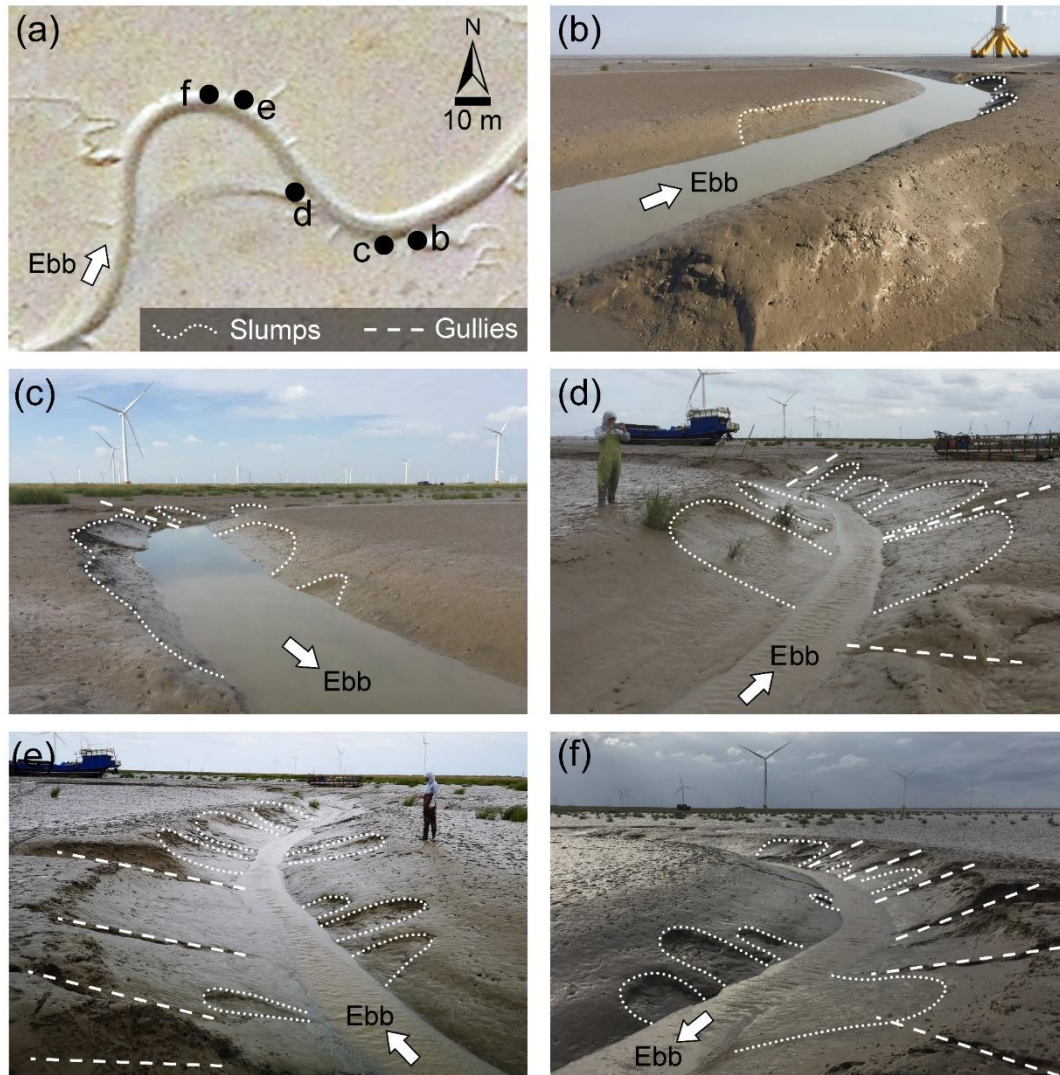

727

728 Figure 13. Bank erosion along the studied channel. (a) Locations of the photographs. (b,c,d,e,f) Close-up views of

729 bank slumps (white dotted lines) and gullies (white dashed lines) along the studied channel. All photos were taken

730 during ebb tides.

731

732 If, on the one hand, bank collapses driven by seepage flow are also commonly documented in

733 vegetated macrotidal settings (Cosma et al., 2022; Zhao et al., 2022) and are therefore more closely

734 linked to sustained tidal oscillations, on the other hand, the abundant erosional gullies (Figure 13)

735 observed at channel banks are most likely specific of unvegetated settings. The formation of such

736  gullies, which can significantly contribute to bank erosion processes, is promoted by strong erosion

737  at the ebb-bankfull transition and favored by the absence of vegetation cover (Guimond &

738  Tamborski, 2021). Bank collapses and gullies can also be counterintuitively related to the presence

739  of cohesive extracellular polymeric substances (EPS) generated by microorganisms abundant on

740  intertidal flats. However, although EPS are widely regarded as bed "stabilizers" (Flemming &

741  Wuertz, 2019), recent flume experiments show that they may enhance sediment mobility under

742  wave actions, inducing liquefaction of otherwise stable bank sediment (Chen et al., 2021), with

743  clear implications for the dynamics of meandering tidal channels.

744  Overall, our results support the idea that meander evolution in intertidal mudflats might not be

745  necessarily correlated with classic curvature-induced helical flows at near-bankfull stages, and that

746  other ecomorphodynamic factors, most likely related to tidal hydrodynamics at late-ebb stages,

747  can be more relevant for meander morphodynamics. A synthesis of the main hydrodynamic

748  characteristics of meandering channels developed in vegetated and unvegetated intertidal plains,

749  and the differences thereof, is reported in Table 2. In addition, a conceptual summary sketch

750  illustrating the major hydrodynamic and morphodynamic differences between tidal meandering

751  channels in vegetated and unvegetated contexts is shown in Figure 14. Further analyses will be

752  needed to corroborate the inferences presented in this study, as well as to investigate the role played

753  by different tidal amplitudes on the processes we described here, especially in terms of distinct

754  hydrodynamic behavior between above and below-bankfull stages. Nonetheless, large tidal ranges

755  (relative to characteristic wind-wave heights) are needed for the development of intertidal mudflats

756  (e.g., Friedrichs, 2011; Klein, 1985; Morales, 2022), so we argue that the processes observed in

757  the present study are likely to be common also in intertidal mudflat channels different from the

758  study case we analyzed here.

759

760

761

762

763

764      Table 2. Comparison of the major hydrodynamic characteristics of meandering tidal channels

765      wandering through vegetated (e.g., salt marshes) and unvegetated (e.g., mudflat) intertidal plains

|  | *Vegetated intertidal plains* | *Unvegetated intertidal plains* |
|---|---|---|
| Overbank flow | Low frequency of occurrence (only for the highest tides) | High frequency of occurrence (almost every tidal cycle) |
|  | Relatively shallow water depth ($Y_{MAX}$<1 m) | Relatively large water depths ($Y_{MAX}$>3-4 m) |
|  | Weak and frictionally-dominated flow ($v_{MAX}$ =0.1-0.2 m/s) | Strong and sheet-flow-dominated flow ($v_{MAX}$ >0.4-0.5m/s) |
|  | Flow direction nearly perpendicular to the channel-axis orientation | Flow direction virtually unrelated to the channel-axis orientation |
| Stage-velocity relation | Higher velocities for above-bankfull stages ($Y>Y_B$) | Higher velocities for below-bankfull stages ($Y<Y_B$) |
| Secondary circulations | Relatively strong. More pronounced when primary streamwise flows are stronger (i.e., in phase with streamwise flows) | Relatively weak. More pronounced when primary flows are weaker (i.e., out of phase with streamwise flows) |
| Helical flow | Well developed | Poorly developed |
| Flow separation | Possible as a function of bend geometry and tidal flow characteristics (i.e, Froude number) | Possible as a function of bend geometry and tidal flow characteristics (i.e, Froude number) |
| Rainfall runoff | Limited importance due to the presence of vegetation | Potentially significant due to the absence of vegetation |
| Wave action on intertidal plains | Weak due to wave attenuation by vegetation | Strong due to high overbank water depths and reduced friction |

766

767

Figure 14. Conceptual sketch depicting the major differences of hydrodynamic processes observed in tidal channels dissecting vegetated (i.e., salt marshes, left columns) and unvegetated (i.e., mudflats, right columns) intertidal plains. (a, b) Channel hydrodynamics during below-bankfull water stages, with particular reference to early-flood and late-ebb stages; (c, d) Channel hydrodynamics at the bankfull stage; (e, f) Channel hydrodynamics during overbank stages.

774 **6 Conclusions**

775 This study contributes to the understanding of hydrodynamic flow structures, and related

776 morphodynamic evolution, in meandering channels wandering through unvegetated tidal flats.

777 Hydroacoustic measurements were carried out, for several tidal cycles, at distinct locations along

778 a mudflat meander bend found within the macrotidal Yangkou tidal flat (Jiangsu province, China).

779 The main conclusions of this research can be summarized as follows:

780 (1) Stage-velocity relationships in mudflat channels are different from those observed in channels

781      wandering through vegetated intertidal plains (i.e., salt marsh and mangrove forests).

782      Specifically, while in the latter case both ebb and flood velocities tend to be higher for above-

783      bankfull water stages, in our study case we observed significantly larger velocities when tidal

784      flows remained confined within the channel banks. This is likely because, in vegetated

785      intertidal plains, both frictionally-dominated flow propagation and higher elevation of channel

786      banks (relative to tidal excursions) ensure flow confinement and high in-channel velocities

787      even for above-bankfull stages. In contrast, in unvegetated intertidal mudflats, similar flow

788      resistance within and outside channels and lower elevation of channel banks produce

789      widespread sheet flow at above-bankfull stages and limit in-channel velocities due to reduced

790      flow confinement;

791 (2) Secondary currents appear to be mostly related to flood flows, and are generally stronger

792      during overbank stages. In some cases, however, the orientation of secondary circulations is

793      reversed compared to classic flow models in meander bends. Poorly-developed secondary

794      circulations are observed at the bend apex. However, primary flow separation, coupled with

795      localized flow measurements that did not include the entire channel cross-section, have likely

796      limited our ability to detect secondary circulation cells during our field measurements.

797 (3) Field data collectively suggest limited control of curvature-induced helical flows on meander

798      morphodynamics. This is most likely due to a consistent phase lag between maxima of primary

799      (i.e., streamwise) and secondary (i.e., cross-sectional) velocities. Such a lag effectively limits

800      the landward (seaward) transfer of secondary flows during the flood (ebb) phase, thus

801      hampering the formation of coherent helical flow structures along the entire meander bends.

802      These findings support the results of earlier studies that suggested that, in stark contrast with

803      both river and salt-marsh meandering channels, meander morphodynamics in intertidal

804    mudflats are poorly related to bankfull hydrodynamics, in general, and curvature-induced

805    helical flows in particular.

806    (4) We suggest that other morphodynamic processes drive the evolution of intertidal mudflat

807    meander bends. Late-ebb tidal flows likely exert strong control on meander morphodynamics

808    due to sustained velocities and pronounced seepage flows, which determine significant

809    sediment transport as well as both bank undercutting and collapses. These effects are also

810    possibly amplified by the absence of vegetation both within and outside the channel, as well

811    as by significant bioturbation of the channel banks, which reduces bank resistance to erosion

812    and enhances seepage flow. In addition, storm waves and both episodic and seasonal increases

813    in discharges due to heavy rainfalls (e.g., related to the monsoon season) and melting snows

814    can compound the morphological effects of late-ebb flows, producing abrupt morphologic

815    changes and pronounced channel migration.

816    Additional field and modeling efforts would be required to corroborate the inferences presented in

817    this study and to investigate how different tidal ranges and channel-bank elevations (relative to

818    characteristic tidal oscillations) affect mudflat meander hydrodynamics and the related

819    morphodynamic evolution. Particularly, cross-sectional measurements of tidal flow fields are

820    needed to directly assess the scarce development of curvature-induced helical flows, whereas

821    repeated measurement of flow fields during normal conditions and heavy rainfall events, coupled

822    with morphological monitoring of channel bank evolution, would help clarify the relative

823    importance of astronomic and meteorological forcings on the morphodynamics of intertidal

824    mudflat meanders.
