10 **Abstract**

11 The elemental stoichiometry of particulate organic carbon (C), nitrogen (N), and phosphorus (P)
12 connects the C fluxes of biological production to the availability of the limiting nutrients in the
13 ocean. It also influences the marine food-web by modulating the feeding behavior of zooplankton and
14 the decomposition of organic matter by bacteria and viruses. Despite its importance, there is a general
15 paucity of information on how the global C:N:P ratio evolves seasonally and interannually, and large
16 parts of the global ocean remain devoid of observational data. Here, we developed a new method that
17 combines satellite ocean-color data with a cellular trait-based model to characterize the spatio-
18 temporal variability of the phytoplankton stoichiometry in the surface mixed layer of the ocean. Here,
19 we demonstrated this method specifically for the C:P ratio. The approach was applied to
20 phytoplankton growth rates and chlorophyll-to-carbon ratios derived from MODIS-*Aqua* and to maps
21 of temperature-dependent nutrient limitation in order to generate global and seasonal maps of upper-
22 ocean phytoplankton C:P. Taking it a step further, we determined the C:P of the bulk particulate
23 organic matter, using MODIS-*Aqua* estimates of particulate organic carbon and phytoplankton
24 biomass. A reasonably good comparison of our results with available data, both horizontal
25 distributions and time series, indicates the viability of our new method in accurately quantifying
26 seasonally resolved global ocean bulk C:P. We anticipate that the new hyperspectral capabilities of
27 the NASA's PACE (Plankton, Aerosol, Cloud, ocean Ecosystem) mission will facilitate the
28 determination of phytoplankton stoichiometry for different size classes and can further enhance the
29 predictability of marine ecosystem stoichiometry from space.

30 **1   Introduction**

31 Ever since Redfield first reported on it more than 85 years ago (Redfield, 1934), the C:N:P ratio of
32 particulate organic matter (POM) has been widely assumed to be stable. A fixed C:N:P ratio has long
33 played a central role in ocean biogeochemistry because this ratio largely determines the strength of
34 the biologically-mediated ocean carbon cycle. However, recent studies show convincingly that the
35 C:N:P stoichiometry of POM varies substantially on ocean-basin scales. For example, Martiny et al.
36 (2013) showed a globally coherent pattern, with C:N:P ratio of 195:28:1 in the subtropical gyres,
37 137:18:1 in the warm upwelling zones, and 78:13:1 in the nutrient-rich polar regions. An inverse

38   model of ocean biogeochemistry also inferred a similar spatial pattern of the global C:P and N:P
39   ratios (Teng et al., 2014; Wang et al., 2019).

40   As carbon export is inversely related to atmospheric CO_2 (Volk and Hoffert, 1985), carbon-enriched
41   particulate organic matter in subtropical gyres could lead to lower atmospheric CO_2 and higher
42   export production of carbon, thereby influencing climate (Galbraith and Martiny, 2015; Tanioka and
43   Matsumoto, 2017; Matsumoto et al., 2020; Ödalen et al., 2020). The ocean carbon modeling
44   community is beginning to respond to this development. For example, the state of the art CMIP5/6
45   models developed by various climate modeling teams around the world represent phytoplankton
46   stoichiometry with varying degree of flexibility, from no flexibility (i.e., fixed C:N:P ratio) to fully
47   flexible (e.g., Bopp et al., 2013; Arora et al., 2020).

48   A major challenge to adopting fully flexible stoichiometry in biogeochemical models is our current
49   inability to observationally constrain the temporal variability of the C:N:P in the global ocean.
50   Although some progress has been made to explore a temporal shift in C:N:P using local time-series
51   data (Hebel and Karl, 2001; Karl et al., 2001; Singh et al., 2015; Martiny et al., 2016; Talarmin et al.,
52   2016), our holistic global view of the global C:N:P ratio variation is still unclear. In-situ C:N:P
53   measurements of POM inherently suffer from bias towards regions and periods of active
54   oceanographic research, and large parts of the global ocean remain devoid of data. For example, there
55   is a considerable paucity of POM sampling efforts in the South and Equatorial Atlantic regions
56   (Sharoni and Halevy, 2020).

57   The remote sensing using satellite ocean-color sensors have the potential to provide a unique tool to
58   constrain the temporal evolution of organic matter C:N:P ratio. Ocean color provides global, synoptic
59   views of the spectral remote-sensing reflectance of the ocean that can be used to generate estimates
60   of marine inherent optical properties (IOPs) at various timescales (Werdell et al., 2018). Satellite
61   ocean color (i.e., remote-sensing reflectance) provides an unparalleled tool to capture climate-driven
62   signals in the upper biological functions of the global ocean (Dierssen, 2010; Dutkiewicz et al.,
63   2019), and has the potential to yield crucial information on the modes of C:N:P variability. Indeed,
64   previous field studies have shown that C:N:P ratio is significantly influenced by interannual climate
65   variabilities such as ENSO and Pacific Decadal Oscillation (Martiny et al., 2016; Fagan et al., 2019).

66   One possible approach to assess the spatio-temporal variability in the C:N:P of POM is to directly
67   estimate the change in the total concentration of particulate organic carbon (POC), particulate organic
68   nitrogen (PON), and particulate organic phosphorus (POP) using satellite ocean color data. Multiple
69   methods of estimating total POC from satellite ocean color have been developed over the years, and
70   the satellite estimates are extensively calibrated with in-situ measurements (Evers-King et al., 2017).
71   More recently, Fumenia et al. (2020) have developed a method to link the backscattering coefficient
72   of (b_{bp}) at 700 nm with PON and POP concentrations in the oligotrophic Western Tropical South
73   Pacific. However, the reliability of b_{bp} as a quantitative proxy of PON and POP still needs to be
74   investigated in other oceanographic areas, including non-oligotrophic regions.

75   Another possible approach of deriving C:N:P of bulk POM is to predict the elemental composition of
76   phytoplankton and use it as a proxy for the bulk composition, assuming phytoplankton make up the
77   largest proportion of POM. The study by Arteaga et al. (2014) showed a seasonally variable global
78   C:N:P ratio of phytoplankton by using a combination of remote sensing data and a mechanistic
79   growth-model of phytoplankton (Pahlow et al., 2013). More recently, Roy (2018) developed a
80   method to estimate the macromolecular content of phytoplankton protein, carbohydrate, and lipid via
81   satellite ocean color by using empirical relationships between the particulate backscattering

82   coefficient, phytoplankton cell size, and cellular macromolecular concentrations. However, this
83   method cannot derive phytoplankton C:P as there is no empirical link between cell size and P-rich
84   macromolecules such as RNA and DNA. Furthermore, a fundamental limitation in both of these
85   studies is that the elemental composition of phytoplankton may not be able to explain the full
86   dynamics of bulk POM because, in reality, phytoplankton biomass typically constitute only 30~50%
87   of bulk particulate organic matter in the open ocean (Eppley et al., 1992; Durand et al., 2001;
88   Gundersen et al., 2001; Behrenfeld et al., 2005).

89   Here, we propose a new remote-sensing approach that uniquely combines established methodologies
90   in order to understand the spatio-temporal variability of the upper-ocean stoichiometry of
91   phytoplankton and bulk POM (Figure 1). Although we only demonstrate the feasibility of this
92   method for C:P ratio in this paper, the framework can theoretically be expanded to include C:N and
93   N:P ratios. In this approach, we first determine C:P of phytoplankton by combining satellite-derived
94   estimates of growth rate, Chl:C ratio, and nutrient depletion temperatures (NDTs) with a newly
95   developed mechanistic model of phytoplankton stoichiometry (Inomura et al., 2020). We then
96   convert phytoplankton C:P ratio to the total POC:POP using remotely sensed concentrations of
97   phytoplankton biomass and POC. This approach is unique in that all inputs are derived from satellite
98   remote sensing and does not rely on in-situ measurements, thereby enabling us to predict the "real-
99   time" evolution of phytoplankton and bulk POM C:P on various temporal and spatial scales of
100   interest.

101   The Methods section of this paper describes this new satellite-informed framework for predicting C:P
102   ratios in the mixed layer. The Results and Discussion section then describes the implementation of
103   our framework to available satellite data and their derived quantities. We discuss the relative
104   importance of the two main drivers of POC:POP variability: (1) variability due to change in
105   phytoplankton C:P that reflect changes in environmental condition such as nutrient supply (e.g..,
106   Garcia et al., 2018; Martiny et al., 2013), and (2) variability due to change in community plankton
107   composition (e.g., Sharoni & Halevy, 2020; Talmy et al., 2016; Weber & Deutsch, 2010). Finally, we
108   discuss caveats, limitations, and future directions. Our ultimate goal in this paper is to demonstrate
109   the feasibility of the method, given all the assumptions and limitations. We envision that future
110   advances in satellite instrumentation will enhance the accuracy of satellite-derived input parameters
111   and will thus improve the overall estimate of C:N:P from space.

112   **2   Methods**

113   **2.1   Satellite-Informed Modeling Framework**

114   The flowchart shown in Figure 1 provides an overview of how we determine phytoplankton C:P and
115   bulk POC:POP ratios from satellite products (ocean color, SST). In the sections below, we briefly
116   describe the phytoplankton stoichiometry model and the method of estimating the bulk C:P of POM.

117   **2.1.1 Phytoplankton Stoichiometry Model**

118   In this study, we determined the C:P ratio for a single phytoplankton functional type using the
119   recently developed phytoplankton stoichiometry model (Inomura et al., 2020). The phytoplankton
120   stoichiometry model of Inomura et al. (2020) is conceptually simple but facilitates the accurate
121   computation of phytoplankton C:P and C:N ratios under a variety of environmental conditions. The
122   input variables required in calculating phytoplankton C:P are light intensity, growth rate, and the
123   presence/absence of limiting nutrients. The model is based on four empirically supported lines of
124   evidence: (1) a saturating relationship between light intensity and photosynthesis, (2) a linear

125 relationship between RNA-to-Protein ratio and growth rate, (3) a linear relationship between
126 biosynthetic proteins and growth rate, and (4) a constant macromolecular composition of the light-
127 harvesting machinery. Also, it follows from these assumptions that chlorophyll-to-carbon ratio
128 ($Chl{:}C_{phyto}$) and growth rate are directly linked for any given light intensity (Laws and Bannister,
129 1980). Inomura et al. calibrated their model parameters subject to constraints provided by data from
130 published laboratory chemostat studies for several key prokaryotic and eukaryotic phytoplankton
131 species. For this study, we used the model parameter set for the cyanobacteria *Synechococcus*
132 *linearis* because the parameters for this species were most rigorously calibrated with laboratory data
133 compared to the other two possible options (cf. a diatom, *Skeletonema costatum,* and a haptophyte,
134 *Pavlova lutheri*). Also, picocyanobacteria such as *Synechococcus* and *Prochlorococcus* are the most
135 abundant phytoplankton types in the global ocean (Flombaum et al., 2013; Berube et al., 2018). Thus,
136 if we are choosing a single group of phytoplankton to represent the whole phytoplankton community,
137 as we do in this study, *Synechococcus* would be a reasonable choice. However, as this particular
138 species of *Synechococcus* is a freshwater species, further calibration efforts specific to the marine
139 cyanobacteria species would be necessary. A complete description and evaluation of the
140 phytoplankton stoichiometry model are provided in the original model description paper (Inomura et
141 al., 2020).

142 In order to determine phytoplankton C:P, we made three minor modifications to the original
143 stoichiometry model by Inomura et al. (2020). First, we drove the stoichiometry model directly with
144 depth-integrated $Chl{:}C_{phyto}$ in the mixed layer obtained from the satellite ocean color instead of
145 calculating $Chl{:}C_{phyto}$ as a function of photon-flux density. This way, we could circumvent the need
146 to estimate depth-dependent irradiance, which is complicated by issues such as self-shading and
147 particle scattering (Jamet et al., 2019). Second, we imposed a fixed maximum growth rate of 2 d^{-1} in
148 calculating C:P, which is equal to the maximum growth rate commonly imposed on the satellite-
149 based estimates of growth rate (Westberry et al., 2008; Laws, 2013). Third, we disregarded the
150 elemental composition in terms of C:N. This last simplification made it possible to circumvent the
151 need to determine whether the cell is P-limited or N-limited based on the external nutrient supply.
152 With this third modification, C:P is fixed at a constant value of 102 under P-replete condition
153 regardless of the P supply, and C:P is stoichiometrically flexible under P-limited condition. We note
154 that under P limitation, the internal P storage inside the cell becomes zero so that the stoichiometry
155 model, by default, does not require information on external nutrient concentration in calculating
156 cellular C:P. With these three modifications, we were able to predict phytoplankton C:P using only
157 satellite ocean color products as inputs.

2.1.2 Satellite-Derived Inputs

159 We drove the modified Inomura model with satellite-derived growth rates (μ), $Chl{:}C_{phyto}$ (a measure
160 of light intensity), and phosphate limitation (via phosphate depletion temperature) to estimate
161 phytoplankton C:P ($r_{C:P}$) in the surface mixed layer (Equation 1):

$$r_{C:P} = C_{phyto}/P_{phyto} = f(\mu, Chl{:}C_{phyto}, SST) \tag{1}$$

163 The required input data in Equation (1) are monthly binned and averaged observations from the *Aqua*
164 Moderate Resolution Imaging Spectroradiometer (MODIS-*Aqua*) acquired from January 2003 to
165 December 2018 and re-gridded on a regular 1°-latitude by 1°-longitude grid. All satellite-derived
166 input data and estimates of mixed-layer depth are available for download from the Oregon State

167 Ocean Productivity Website (http://sites.science.oregonstate.edu/ocean.productivity/index.php, last
168 access: June 22, 2020).

169 The carbon-based specific growth rate μ (measured in d^{-1}) is estimated by dividing the depth-
170 integrated net primary productivity (NPP, measured in mg C m^{-2} d^{-1}) by the standing stock of
171 phytoplankton carbon (C_{phyto}, measured in mg C m^{-2}):

172 $$\mu = NPP/C_{phyto} \tag{2}$$

173 There are multiple NPP data products available to date (Westberry and Behrenfeld, 2014; Bisson et
174 al., 2018). In order to illustrate the robustness of our C:P determination to the choice of the NPP
175 products, we used the following four NPP satellite data products: (1) the Carbon, Absorption and
176 Fluorescence Euphotic-resolving model (CAFE) (Silsbe et al., 2016), (2) the Vertically Generalized
177 Productivity Model (VGPM) (Behrenfeld and Falkowski, 1997), (3) the Eppley-VGPM Model
178 (Eppley, 1972; Behrenfeld and Falkowski, 1997), and (4) the Carbon-based Productivity Model
179 (CbPM) (Westberry et al., 2008). A previous study showed that CAFE compares best with in-situ
180 NPP measurements (Bisson et al., 2018). Because the growth rates from VGPM, Eppley-VGPM, and
181 CbPM are similar quantitatively (Supplementary Figure 1), we only present results from VGPM as
182 representing the three models in the main text. Throughout the text, we use the phrases "CAFE-
183 informed phytoplankton C:P" and "VGPM-informed phytoplankton C:P" to refer to C:P calculated
184 using μ from CAFE-based NPP and VGPM-based NPP, respectively.

185 For C_{phyto}, we used the satellite data product of Westberry et al. (2008), who computed C_{phyto} as a
186 linear function of the particulate backscatter coefficient at 443 nm, $b_{bp}(443)$. We only considered a
187 single algorithm of C_{phyto} in this study because the previous intercomparison study showed that no
188 single algorithm outperforms any of the other algorithms when compared with in-situ data (Martínez-
189 Vicente et al., 2017). We excluded from our analyses the coastal regions with C_{phyto} exceeding 1000
190 mg C m^{-3} and we multiplied the monthly mean surface concentration of C_{phyto} with monthly mean
191 mixed layer depth (MLD) from the Hybrid Coordinate Ocean Model (HYCOM) to get the depth-
192 integrated C_{phyto}. Here, MLD is defined as the depth where the density of water is greater than that of
193 water at a reference depth of 10 m by 0.125 kg m^{-3} (Levitus, 1982). The growth rate calculated this
194 way in Equation (2) is representative of a well-mixed, photoacclimated community subject to the
195 median PAR in the mixed layer. The satellite-derived seasonal variability in μ reflect changes in light
196 and nutrient limitation, as well as phytoplankton community composition (Behrenfeld et al., 2005).

197 Figure 2 shows satellite-derived estimates of μ during summer and winter. CAFE predicts a higher μ
198 during summer months compared to winter months for the large parts of the ocean (Figure 2a-c).
199 VGPM (Figure 2d-f) and the other two NPP products (CbPM and Eppley-VGPM; Supplementary
200 Figure 1) show similar trends in the high latitude but show the opposite trend in the subtropics with
201 lower μ during summer compared to winter. As a result, the range of estimated μ amongst NPP
202 products are higher during the summer (Figure 2g) compared to winter (Figure 2h) and is most
203 extensive in the subtropics. Here, the range is a measure of uncertainty and is given by the difference
204 between the maximum and minimum μ estimates amongst four NPP products. Throughout the rest of
205 this paper, the "summer" average refers to average values during July – September in the Northern
206 Hemisphere and during January – March in the Southern Hemisphere. For the "winter," the target
207 months are reversed between two hemispheres.

208 The *Chl:C_{phyto}* ratio, a proxy for light limitation (Falkowski et al., 1985; MacIntyre et al., 2002), is
209 computed here by dividing MODIS-derived *Chl-a* with C_{phyto}. *Chl-a* concentration is depth-integrated

210 and therefore converted from mg Chl m^{-3} to mg Chl m^{-2} by multiplying the monthly mean surface
211 concentration with monthly mean MLD. Like for growth rate, we assumed that the $Chl:C_{phyto}$ is
212 vertically uniform in the mixed layer. Figure 3a-c shows estimates of $Chl:C_{phyto}$ during summer and
213 winter. In general, $Chl:C_{phyto}$ is higher during winter than summer as the reduced incident irradiance
214 causes phytoplankton to allocate more of the cellular component to the light-harvesting apparatus
215 (Geider, 1987; MacIntyre et al., 2002; Arteaga et al., 2016). High $Chl: C_{phyto}$ in the sunlit layer of the
216 continental margins are known to be relatively inaccurate and biases due to interferences by the high
217 and variable amounts of colored dissolved organic matter (CDOM) and detritus (Siegel et al., 2005;
218 Morel and Gentili, 2009; Loisel et al., 2010). As we excluded coastal regions in the subsequence
219 analyses, this issue should not affect our satellite-informed estimates of C:P.

220 We assessed if there is P limitation by utilizing nutrient depletion temperatures (NDTs), which are
221 temperatures above which nutrients are no longer detectable by traditional wet-chemistry techniques
222 (Zentara and Kamykowski, 1977; Kamykowski and Zentara, 1986). The method leverages an
223 observed inverse empirical relationship between surface nutrient concentration and sea-surface
224 temperature (SST). In this relationship, phytoplankton is considered nutrient-limited if the difference
225 between SST and NDT is higher than 0 and vice versa if the difference is lower than 0. We used a
226 global NDT mask of the percentile-based, cubic root-corrected phosphate depletion temperatures
227 (PDT3) re-gridded to a 1-by-1° spatial resolution (Figure 3f; Kamykowski et al., 2002). We
228 subtracted PDT3 from MODIS-derived monthly mean SST to determine the absence/presence of P
229 limitation in the surface ocean. P limitation as a result of SST exceeding phosphate depletion
230 temperature is globally prevalent during summer (Figure 3d). Phosphate depletion is alleviated
231 during winter months at high latitudes and in some parts of the equatorial regions as the surface
232 ocean cools in part because of enhanced vertical mixing (Figure 3e). For the current work, we limited
233 our study to latitudes ranging from 50°S to 70°N as the original data on PDT3 beyond this latitudinal
234 range are sparse (Kamykowski et al., 2002). We further discuss the caveats and limitations of this
235 approach in Section 3.4.

236 We obtained the MODIS-derived total monthly averaged POC (0.7 μm $< D <$ 17 μm) from the
237 NASA Ocean Color Product webpage (http://oceancolor.gsfc.nasa.gov, last access: June 22, 2020).
238 This total POC determination is based on an empirical relationship between POC and the blue-to-
239 green band of spectral remote-sensing reflectance (Stramski et al., 2008). The algorithm employed
240 here is widely implemented for producing maps of surface POC. The global mean C_{phyto}:POC is ~
241 30% (Figure 3g-h), consistent with previous estimates (Behrenfeld et al., 2005). The C_{phyto}:POC is
242 generally higher in the subtropical gyres than other regions reaching up to 50-70% during summer
243 (Figure 3g). C_{phyto}:POC ratio rarely exceeds a value of 1 except during episodic events in coastal
244 regions, which we disregard in our analyses. Although C_{phyto} and POC are independently determined,
245 the fact that C_{phyto}:POC ratio rarely exceeds a value of 1 increases our confidence in the predictability
246 of C_{phyto}:POC.

247 **2.1.3 Estimating C:P of Bulk POM**

248 Globally, phytoplankton derived organic matter represents on average ~30% of bulk organic matter
249 (Eppley et al., 1992; Durand et al., 2001; Gundersen et al., 2001; Behrenfeld et al., 2005), and the
250 rest is due to contributions from zooplankton and non-living detrital materials. In order to estimate
251 C:P of bulk POM, we split the POC and particulate organic phosphorus (POP) into two components:
252 (1) phytoplankton-derived organic matter with C:P ratio following the stoichiometry model in the
253 previous section, and (2) non-algal component with fixed C:P of 117:1 following Anderson and
254 Sarmiento (1994). Throughout the rest of this paper, the "community composition" refers to the

6

255 relative balance between the algal and non-algal components of organic matter, not the community
256 composition of different phytoplankton functional types.

257 The non-algal component of particulate organic matter with fixed C:P represents a combination of
258 zooplankton and other non-living detrital materials such as fecal pellets and other organic matter left
259 over from sloppy feeding (Martiny et al., 2013a, 2013b; Talmy et al., 2016). Previous studies have
260 shown that zooplankton generally has a C:P close to the Redfield ratio even under P-limited
261 conditions (e.g., Copin-Montegut & Copin-Montegut, 1983; Sterner & Elser, 2002). Isopycnal
262 analysis of export and remineralization stoichiometry of the deep ocean (>400 m) also indicates a
263 relatively constant C:P of around ~117 globally (Anderson and Sarmiento, 1994).

264 In calculating the C:P ratio of bulk POM, we solve for three unknowns: (1) the carbon content of
265 non-algal POM, (2) the phosphorus content of non-algal POM, and (3) total POP. This is achieved
266 with three equations:

$$C_{phyto} + C_{non} = POC \tag{3}$$

$$P_{phyto} + P_{non} = POP \tag{4}$$

$$C_{non}/P_{non} = 117 \tag{5}$$

270 The subscript "phyto" refers to the phytoplankton component, and "non" refers to the non-algal
271 component of POM. All the quantities are in mol per unit volume. Equations (3) and (4) describe the
272 conservation of carbon and phosphorus, respectively, and the Equation (5) describes the fixed C:P
273 ratio of non-algal organic matter. Essentially, Equations (3) - (5) constitute a simple two end-member
274 mixing model of the algal and non-algal components. We can obtain C:P of the bulk organic matter
275 as a function of the known quantities from Section 2.1, C_{phyto}, $r_{C:P}$, and total POC by rearranging (1),
276 (3) - (5):

$$POC:POP = \frac{117 \cdot r_{C:P}}{117 \cdot C_{phyto}/POC + r_{C:P} \cdot (1 - C_{phyto}/POC)} \tag{6}$$

278 Equation (6) shows that the bulk C:P ratio is a non-linear function of phytoplankton C:P ($r_{C:P}$) and
279 the relative abundance of C_{phyto} over total POC (C_{phyto}/POC).

2.2 Model-Data Comparison of POC:POP

281 We compared the satellite-informed bulk POC:POP with a recently compiled data set of 5573 in-situ
282 observations of suspended oceanic POC:POP ratios from cruises and other marine stations distributed
283 globally (Martiny et al., 2014). The suspended POM samples were collected on 0.7 μm filters (GF/F),
284 and their C:P ratios reflect contributions from phytoplankton, microzooplankton, detrital material,
285 and mixed particle aggregates. Here, we only used samples from the upper 100 m of the water
286 column, representative of an average mixed layer (Kara et al., 2003) and excluded samples with POP
287 concentrations inferior to the reported detection limit of 5 nM. We also removed samples from
288 coastal waters, which often include a substantial contribution of allochthonous POM (e.g., benthic,
289 riverine) (Liénart et al., 2018).

290 When comparing the large-scale temporal variability of in-situ C:P with satellite estimates, we
291 binned the measured C:P data into 10°-latitude increments. At each sampling station, we calculated
292 the mean C:P in the top 100 m. After this screening process, we were left with 185 observational

293   points for summer and 111 observational points for winter (Figure 4). We compared the seasonally-
294   averaged, satellite-informed POC:POP with the C:P of suspended POM spanning from 50°S to 70°N.

295   To further evaluate the performance of our modeling framework, we compared our satellite-informed
296   estimates of C:P to direct POC:POP measurements at the BATS and HOT sites. The time-series data
297   of POC and POP measurements from these two stations are included in the global POM database.
298   Here, we selected data in the top 100 m that were collected between 2003 – 2010 for the "point-to-
299   point" comparison with the satellite estimates of C:P.

3   Results and Discussion

3.1   Large-scale Seasonal Variability in Phytoplankton C:P

302   Combining the estimates of growth rate, $Chl:C_{phyto}$, and P limitation can help determine the seasonal
303   variability in phytoplankton C:P (Figure 5). The satellite-informed $r_{C:P}$ is highest in the stratified
304   oligotrophic gyres and lowest in the higher-latitude, seasonally stratified seas and equatorial
305   upwelling regions, consistent with existing field observations (Martiny et al., 2013a). Both the CAFE
306   (Figure 5a-c) and VGPM-informed $r_{C:P}$ (Figure 5d-f) show elevated $r_{C:P}$ in the higher-latitude region
307   during the summer months compared to the winter months as ocean warming enhances stratification
308   and phytoplankton becomes P-limited. The increase in light availability during summer, shown by a
309   decrease in $Chl:C_{phyto}$, also helps in increasing $r_{C:P}$ at higher-latitude regions.

310   Although the spatio-temporal pattern of phytoplankton C:P is consistent across four satellite-
311   informed cases for high-latitude regions and equatorial regions (Supplementary Figure 2), the range
312   of the four satellite $r_{C:P}$ estimates is large in the subtropics (Figure 5g-h). This larger range reveals a
313   relatively large uncertainty in $r_{C:P}$ in the subtropics. Considering that the oligotrophic gyres tend to be
314   P-limited throughout the year and the change in $Chl:C_{phyto}$ is small, large uncertainties in μ are
315   predominantly responsible for this uncertainty in $r_{C:P}$ in those regions of the global ocean. While the
316   CAFE-informed $r_{C:P}$ shows a noticeable decrease during summer by ~100-200 molar units (Figure
317   5c), VGPM-informed $r_{C:P}$ shows an increase during summer (Figure 5f).

318   In theory, $r_{C:P}$ should decrease as growth rate increases, and the fractional change in $r_{C:P}$ should be
319   highest for low growth (Droop, 1974; Burmaster, 1979; Goldman et al., 1979; Morel, 1987). In other
320   words, a small change in growth rate should lead to a large change in $r_{C:P}$ when the growth rate is
321   low. Multiple culture experiments support this prediction, where phytoplankton growing at a high
322   rate is both P-rich and has reduced stoichiometric flexibility (e.g., Hillebrand et al., 2013). If we
323   assume P-limited growth condition and replace growth rate with PO_4 concentration, this pattern
324   would also be true for PO_4 vs. $r_{C:P}$ where phytoplankton growing under low P environment are frugal
325   (high $r_{C:P}$) and more stoichiometrically flexible (Galbraith and Martiny, 2015; Tanioka and
326   Matsumoto, 2017, 2020). As subtropical regions are strongly P limited and the growth is suppressed
327   (Wu et al., 2000; Martiny et al., 2019), this reasoning can explain the elevated $r_{C:P}$ with large
328   uncertainty and sensitivity.

329   Figure 6 illustrates how $r_{C:P}$ varies under varying growth rates and $Chl:C_{phyto}$ in specific regions.
330   Contour lines (isopleths) representing the theoretical values of $r_{C:P}$ are predicted by the Inomura
331   phytoplankton stoichiometry model for different combinations of μ and $Chl:C_{phyto}$ under the P limited
332   scenario. In order to illustrate the regional variability, we superimposed monthly averaged, CAFE-
333   informed $r_{C:P}$ in four oceanographic regions. These four regions are: (1) the high latitude bloom-
334   forming North Atlantic Ocean (NAT: 25°W - 35°W, 45°N - 50°N), (2) the North Atlantic subtropical

335   gyre (NASG: 25°W-70°W, 25°-35°N), (3) the South Pacific subtropical gyre (SPSG: 90°W-150°W,
336   15°S-40°S), and (4) the Equatorial upwelling region (EQU: 5°S - 5°N), following Westberry et al.
337   (2016). The size of the symbol indicates the extent of P limitation. "P-replete" symbolizes < 20% of
338   grid boxes in the region are P-limited, "Moderate" symbolizes 20% – 80% , and "Deplete" > 80%
339   based on the seasonally varying SST. The numbers represent the month of the year.

340   There are two key features in this plot. The first is that different oceanographic regions occupy a
341   unique space. For example, North Atlantic (NAT) experiences large seasonal variability in growth
342   rate, P limitation, and $r_{C:P}$, while EQU experiences small seasonal changes. The second important
343   feature is that the contours representing $r_{C:P}$ become increasingly close together as the growth rate
344   decreases. This reiterates the fact that a small change in satellite-derived growth rate can lead to a
345   large change in $r_{C:P}$ at chronically nutrient-deplete subtropical gyres (NASG and NPSG).

346   Light availability also affects $r_{C:P}$ as light modulates the cellular allocation between light-harvesting
347   apparatus, biosynthetic apparatus, and energy storage reserves (Falkowski and LaRoche, 1991;
348   Moreno and Martiny, 2018). The Inomura phytoplankton stoichiometry model predicts that increased
349   light limitation increases cellular allocation toward photosynthetic proteins and decreases allocation
350   toward C-rich biosynthetic proteins. Therefore, an increase in $Chl:C_{phyto}$ (i.e., increased light
351   limitation) will lead to a decrease in $r_{C:P}$ at a constant growth rate (Figure 6).

352   As expected, satellite-derived $Chl:C_{phyto}$ indeed shows maxima during winter months (January-March
353   in Northern Hemisphere and July-September in Southern Hemisphere) due to decreased exposure to
354   sunlight (Figure 6). As shown in previous modeling studies, the effect of light on $r_{C:P}$ is
355   disproportionally large when the growth rate is low, and an increase in $Chl:C_{phyto}$ can effectively
356   reduce $r_{C:P}$ during winter months (Arteaga et al., 2014; Talmy et al., 2014). Compared to the growth
357   rate, however, the effect of light limitation on $r_{C:P}$ is weak, as shown by the vertically steep contour
358   lines in Figure 6. Indeed, a meta-analysis on published laboratory studies has shown that the effects
359   of light on $r_{C:P}$ are significantly weaker than that of macronutrients and temperature (Tanioka and
360   Matsumoto, 2020).

361   **3.2   Large-scale Seasonal Variability in Bulk POC:POP**

362   By combing the satellite-informed phytoplankton C:P and the community composition measured by
363   C_{phyto}:POC, we can determine POC:POP of the bulk POM (Figure 7). Similar to $r_{C:P}$, bulk POC:POP
364   ratios are highest in the gyres compared to the equatorial upwelling and high-latitude regions.
365   Globally, satellite POC:POP is higher during the summer compared to the winter. This seasonal trend
366   can be explained by the higher C_{phyto}:POC during summer than winter (Figure 3i). This makes
367   intuitive sense because the phytoplankton biomass concentration is kept low in the mixed layer
368   during winter months due to the deepening of MLD, strong light limitation, and zooplankton grazing
369   (Behrenfeld and Boss, 2018). As C:P of P-limited phytoplankton is higher than C:P of non-algal
370   organic matter, increase in C_{phyto}:POC during summer leads to an increase in POC:POP. The most
371   noticeable increase is visible in the South Pacific Subtropic Gyre, where summertime POC:POP is
372   higher than the winter value by ~200 as C_{phyto}:POC increases by ~50% during summer compared to
373   winter. The range (uncertainty) in satellite-informed POC:POP (Figure 7g-h) is much smaller
374   compared to that of phytoplankton C:P (Figure 5g-h), and all the four satellite-informed estimates

375 agree on a general increase in POC:POP during summer compared to winter (Figure 7i,
376 Supplementary Figure 3).

377 Figure 8a illustrates how the bulk POC:POP is nonlinearly related to the community composition
378 (measured by C_{phyto}:POC) for a given change in $r_{C:P}$. We observe from the satellite-derived data of
379 C_{phyto} and POC that C_{phyto}:POC is, on average, ~30% and rarely exceeds 50% of the total POC pool.
380 The increase in POC:POP with respect to increase in $r_{C:P}$ reaches a plateau quickly when C_{phyto}:POC
381 < 30%. In other words, the community dominance of non-algal POM over algal POM can effectively
382 put a cap on the increase in bulk POC:POP, even when phytoplankton C:P is very high (e.g., NASG
383 and SPSG). This top-down control on POC:POP due to community composition also explains the
384 low uncertainty in the estimates of satellite-informed POC:POP despite the large uncertainty in
385 satellite-informed $r_{C:P}$.

386 Figure 8b is an alternative way of illustrating this top-down control on bulk POC:POP by community
387 composition. Contour lines representing POC:POP based on our simple two end-member algal/non-
388 algal mixing model are widely separated when C_{phyto}:POC is low, indicating that POC:POP is
389 relatively stable when C_{phyto}:POC is relatively low. On the other hand, when C_{phyto}:POC is high,
390 contour lines become closer together, and bulk POC:POP quickly approaches $r_{C:P}$. If we plot
391 monthly-averaged estimates of satellite-derived bulk POC:POP under different regions, two distinct
392 clusters become apparent. Subtropical gyres (NASG and SPSG) are characterized by high $r_{C:P}$ and
393 C_{phyto}:POC resulting in sizeable seasonal variability in bulk POC:POP. On the other hand, NAT and
394 EQU experience a smaller seasonal change in POC:POP as the C_{phyto}:POC remains relatively
395 constant around 15%. The take-home message from Figure 8 is that a community composition can
396 exert a strong top-down control on POC:POP even when phytoplankton C:P is much higher than the
397 Redfield ratio. Indeed, multiple studies emphasize this point, including recent studies on C:N (e.g.,
398 Talmy et al., 2016), N:P (e.g., Sharoni and Halevy, 2020), as well as the original study by Redfield et
399 al. (1963).

3.3 **Model-Data Comparison**

401 In order to assess our model predictions, we first compare our seasonally-resolved zonally averaged
402 satellite POC:POP estimates with measurements of sampled POC:POP (Figure 9). Globally, both the
403 satellite estimates and the in-situ observations show higher POC:POP in summer (Figure 9a) than in
404 winter (Figure 9b). This increase during summer is likely to be driven by a change in community
405 composition, with an increased C_{phyto}:POC during summer. At high-latitudes, an increase in
406 phytoplankton C:P also drives an increase in POC:POP during summer. Therefore, the combination
407 of the change in community composition and phytoplankton C:P is responsible for the increased bulk
408 POC:POP during summer.

409 Although it is promising that our predictions are mostly consistent with observations, there are two
410 distinct regions where the satellite POC:POP and the observations do not agree. The first is the
411 equatorial region during summer (Figure 9a), where satellite-informed POC:POP is around 150 but
412 observed POC:POP is close to the Redfield ratio of 106. This discrepancy stems from the fact that
413 our method likely overestimates the degree on which the equatorial regions are P-limited, which in
414 turn leads to an overestimation of the phytoplankton C:P to as high as ~200. In addition, our
415 phytoplankton C:P model is tuned to data for *Synechococcus*. In reality, fast-growing opportunistic
416 eukaryotic plankton such as diatoms and other eukaryotes with lower C:P are more predominant in
417 the equatorial region (Arrigo, 2005; Martiny et al., 2013a; Kostadinov et al., 2016). The second
418 region where we observed a noticeable difference between satellite estimates and in-situ observation

419 is around 20°S during winter (Figure 9b). Given the paucity of observations in this region, however
420 (*n* = 12 and 8 for summer and winter, respectively), it is challenging to determine the exact cause for
421 the increase in POC:POP during the winter.

422 To further assess our model capability, we compare time-series data of suspended POC:POP in the
423 top 100 m from BATS and HOT with satellite estimates in the seasonally mixed-layer depth from
424 2003-2010 (Figure 10). It is important to note that suspended POC:POP is a "point" value reflecting
425 elemental composition at a particular location and at a particular time, whereas the satellite-informed
426 POC:POP is a monthly and area-averaged value for a 3-by-3-pixel area around the BATS and HOT
427 stations. We use the median satellite-informed phytoplankton C:P and POC:POP values from four
428 satellite products (CAFE, VGPM, Eppley-VGPM, and CbPM) for comparison with the data.

429 In general, measured POC:POP ratios lie between our satellite estimates of phytoplankton C:P and
430 bulk POC:POP ratios at both BATS and HOT (Figure 10a-b). Measured POC:POP, on average, is
431 closer to the satellite-informed POP:POC than to satellite-informed $r_{C:P}$ (Figure 10c-d). This makes
432 intuitive sense because in-situ observations show that the biomass of picocyanobacteria
433 (*Prochlorococcus, Synechococcus*) only contributes to < ~40% of the POC pool in the gyres (Casey
434 et al., 2013). Qualitatively, our satellite estimates of bulk POC:POP seem to capture the general
435 seasonal variability, with POC:POP being lowest in the winter and highest in the summer and the
436 fall. Also, both the satellite-informed and the observed C:P are lowest in the late winter as a result of
437 deep mixing and increased supply of nutrients, which cause phytoplankton C:P to decrease (Singh et
438 al., 2015). Satellite-informed bulk POC:POP, however, underestimates the observed POC:POP by
439 ~50 on average at BATS (Figure 10c) and ~20 at HOT (Figure 10d), and this may reflect the fact that
440 non-algal organic matter has a higher ratio than Redfield of 117. Also, our satellite-informed estimate
441 may not be fully capturing episodic temporal changes in C:P, for example, during the spring bloom
442 when phytoplankton C:P is expected to increase rapidly (Polimene et al., 2015).

443 The satellite-informed estimates of phytoplankton C:P and POC:POP presented here are still
444 preliminary and, therefore, should not be treated as accurate estimates. Nevertheless, even with this
445 simple two-end-member mixing model approach, we can make a testable hypothesis regarding the
446 underlying mechanisms causing the observed temporal change in suspended POC:POP. First, in
447 order to model temporal shifts in POC:POP, we need to consider the contribution that non-algal
448 organic matter makes to POM as well as the change in phytoplankton C:P. Our results indicate that
449 phytoplankton C:P alone leads to a considerable overestimation of bulk POC:POP, regionally, and
450 globally. Second, our satellite-informed bulk POC:POP can capture the seasonal trend in POC:POP,
451 which shows elevated values during summer compared to winter. We are optimistic that with more
452 sophisticated parameter calibration of the phytoplankton stoichiometry model and non-algal C:P, it
453 will be possible to predict the temporal variability of POC:POP accurately in future studies.

454 **3.4   Caveats, Limitations, and Future Needs**

455 Satellite estimates of phytoplankton and bulk C:P have considerable uncertainty in the subtropical
456 gyres during summer. This mainly stems from the fact that satellite-derived growth-rate estimates are
457 considerably different depending on which NPP product is used. In the future, we also need to
458 conduct careful sensitivity analyses of how different satellite-based algorithms of C_{phyto} and POC
459 would affect satellite-informed estimates of ecosystem stoichiometry. It is inherently challenging to
460 characterize C:P accurately in subtropics with phytoplankton stoichiometry models (Garcia et al.,
461 2020) as phytoplankton turnover happens quickly on a time scale of days (Malone et al., 1993). For a
462 complete understanding of the temporal variability of phytoplankton and bulk C:P, measurements of

463 phytoplankton-specific C:P using high throughput flow cytometry (Graff et al., 2015; Kirchman,
464 2016) or single-probe mass spectrometry (Sun et al., 2018) would be necessary. Linking
465 metagenomics data with the phytoplankton stoichiometry model and remote sensing may also help
466 improve C:P estimates in the subtropics (Garcia et al., 2020).

467 In this study, we used parameters for *Synechococcus*, a cosmopolitan phytoplankton species with a
468 broad biogeographic distribution that extends from tropics to subpolar regions (Flombaum et al.,
469 2013; Berube et al., 2018). This parameterization should be representative of another
470 picocyanobacterium, *Prochlorococcus*. Together, *Prochlorococcus* and *Synechococcus* are
471 responsible for roughly a quarter of the total ocean net primary productivity (Flombaum et al., 2013).
472 Given that the current satellite-derived products cannot easily resolve size-partitioned phytoplankton
473 physiologies such as growth rate and $Chl:C_{phyto}$, it seems reasonable to tune the phytoplankton
474 stoichiometry model to these most common phytoplankton types. With new advances in satellite
475 instrumentation, such as the development of reliable hyperspectral ocean color measurements
476 (Werdell et al., 2018; Schollaert Uz et al., 2019), we may be able to better resolve the size-specific
477 C:P of different phytoplankton functional types. This would enable us to fully capture the spatio-
478 temporal variability of community phytoplankton C:P, particularly in nutrient-rich upwelling and
479 coastal regions where nano- and micro-phytoplankton are more dominant than picophytoplankton
480 (Kostadinov et al., 2016).

481 We inferred the P limitation of phytoplankton by comparing satellite-based SST and the previously
482 compiled mask of nutrient depletion temperature. Although our method can provide a first-order
483 pattern of P limitation, this method cannot resolve the degree to which phytoplankton are P-stressed.
484 In other words, we cannot determine whether the phosphate is the primary or secondary limiting
485 nutrient for phytoplankton growth (Moore et al., 2013). Also, a recent study suggests that we cannot
486 determine for sure that phytoplankton are P-limited even when the observed phosphate concentration
487 is below the detection limit (Martiny et al., 2019). Accurate determination of nutrient concentration
488 from space is inherently challenging (Goes et al., 2000; Steinhoff et al., 2010; Arteaga et al., 2015),
489 and this is one of the major bottlenecks for accurately probing phytoplankton nutrient limitation from
490 space. Although there are no standard protocols or algorithms currently available, we may be able to
491 accurately retrieve surface nutrient concentrations by using advanced statistical and machine learning
492 techniques applied to satellite-retrieved sea surface salinity, temperature, and remote-sensing
493 reflectance (e.g., Wang et al., 2018).

494 A fundamental assumption made when predicting bulk POC:POP is that C:P of non-algal organic
495 matter is constant with a Redfield Ratio of 117. There is a consensus from previous marine and
496 freshwater studies that C:P of heterotrophs is generally lower and more homeostatic (relatively
497 constant) than that of phytoplankton (Elser and Urabe, 1999; Persson et al., 2010). The bulk POM,
498 however, can be modified due to decomposition (Schneider et al., 2003), viral shunt (Jover et al.,
499 2014), preferential remineralization (Shaffer et al., 1999), as well as the interplay between the
500 dissolved and particulate pools. Measuring the elemental composition of separate constituents of
501 organic matter should better help us constrain the most appropriate end-member C:P for non-algal
502 organic matter. Alternatively, we can mechanistically predict C:P of bulk POM by coupling the
503 phytoplankton stoichiometry model with models of prey-predator interaction and decomposition
504 (e.g., Anderson et al., 2005; Butenschön et al., 2016; Tanioka and Matsumoto, 2018).

505 **4   Conclusion**

12

506 We showed that it is possible to determine spatially and temporally coherent patterns of the C:P
507 ratios of phytoplankton and bulk POM using only remotely sensed information. The results shown
508 here should not be treated as accurate estimates of upper-ocean C:P but rather as a feasibility study
509 that can benefit from more accurate remotely sensed estimates of growth rate and from a better
510 understanding of the links between growth rate and stoichiometry in various marine phytoplankton.
511 The data describing the C:P ratio of individual POM components (i.e., algal and non-algal
512 components) is also currently insufficient spatially and temporally to validate our estimates.
513 However, our main conclusion highlighting the importance of community composition in controlling
514 bulk POC:POP does not depend on the accuracy of stoichiometry estimates. This hypothesis has
515 important implications for estimating carbon and phosphorus fluxes to the deep ocean and for the
516 trophic transfer to higher organisms. Indeed, if the POC:POP of exported POM is controlled by
517 community composition rather than phytoplankton C:P, we would not expect large "stoichiometric
518 buffering" of carbon export under climate-change scenarios as proposed by previous studies (Teng et
519 al., 2014; Galbraith and Martiny, 2015; Tanioka and Matsumoto, 2017; Matsumoto et al., 2020). The
520 effect of change in phytoplankton C:P will, however, become more critical for carbon export if the
521 total % of phytoplankton in organic matter increases or of the C:P of non-algal component increases.
522 We hope that the questions raised here will foster collaborative work combining satellite remote
523 sensing, field sampling, and numerical modeling specialists to improve our ability to predict organic
524 matter dynamics and reduce uncertainties in our projections of the future carbon cycle.

525 **5   Conflict of Interest**

526 The authors declare that the research was conducted in the absence of any commercial or financial
527 relationships that could be construed as a potential conflict of interest.

528 **6   Author Contributions**

529 TT, CGF, and KM designed the study. TT gathered and analyzed data. All the authors wrote the
530 manuscript.

531 **7   Funding**

533 **8   Data Availability Statement**

534 MODIS-aqua satellite products can be found at Oregon State Ocean Productivity Website
535 (http://sites.science.oregonstate.edu/ocean.productivity/index.php) and NASA Ocean Color Product
536 Webpage (http://oceancolor.gsfc.nasa.gov). The data set containing POM observations is available at
537 http://www.bco-dmo.org/dataset/526747. The model codes for the phytoplankton stoichiometry
538 model can be found in Zenodo provided by Inomura et al.
539 (https://zenodo.org/record/3679030#.Xz7yt9NKho4).

825 **Figure Captions**

826 **Figure 1:** Flowchart summarizing the modeling framework. White squares represent globally
827 gridded data from MODIS-Aqua and their direct products (NPP, C_{phyto}, and POC). The dashed arrows
828 pointing towards NPP indicate that remotely sensed SST and Chl are used in deriving NPP. Orange
829 boxes are main products from this study; C:P of phytoplankton ($r_{C:P}$) and bulk POC:POP.

830 **Figure 2:** Global climatology of average summer and winter growth rate (μ) in the surface mixed
831 layer derived from the CAFE (a-c) and VGPM (d-f) NPP products. Panels (g) and (h) show the
832 maximum range in the four satellite-derived estimates of μ in summer and winter, respectively. Panel
833 (i) shows the seasonal change in the median value of satellite-derived μ.

834 **Figure 3:** Global climatology of summer and winter surface mixed layer averages for model inputs:
835 (a)-(c) $Chl:C_{phyto}$, (d)-(f) P limitation based on cubic root-corrected phosphate depletion temperature
836 (PDT3), and (g-i) the mass ratio between phytoplankton biomass (C_{phyto}) and total POC in %. PDT3
837 is seasonally invariant, and phytoplankton is P-limited if SST minus PDT3 is greater than 0.

838 **Figure 4:** Geographical locations of suspended POM sample stations used in this study. Red dots
839 represent samples collected in summer months (July-September in the Northern Hemisphere,
840 January-March in the Southern Hemisphere), and blue dots represent samples collected in winter
841 months (January-March in the Northern Hemisphere, July-September in the Southern Hemisphere).
842 Dashed boxes delineate regions where the seasonality of satellite-informed estimate is examined
843 (NAT: North Atlantic Temperate, NASG: North Atlantic Subtropical Gyre, SPSG: South Pacific
844 Subtropical Gyre, EQU: Equatorial Upwelling regions).

845 **Figure 5:** Global climatology of summer and winter average CAFE-informed $r_{C:P}$ (a-c) and VGPM-
846 informed $r_{C:P}$ (d-f) in the surface mixed layer. $r_{C:P}$ is in molar units. Panels (g) and (h) show the
847 maximum range in the four satellite-informed $r_{C:P}$ for summer and winter, respectively. Panel (i)
848 shows the seasonal change in median $r_{C:P}$.

849 **Figure 6:** Influence of growth rate and $Chl:C_{phyto}$ on $r_{C:P}$ under P limitation. Colored points represent
850 seasonally averaged CAFE-informed $Chl:C_{phyto}$, μ, and $r_{C:P}$ for four oceanographic regions (NAT:
851 North Atlantic Temperate, NASG: North Atlantic Subtropical Gyre, SPSG: South Pacific Subtropical
852 Gyre, EQU: Equatorial Upwelling region. The size of marker represents the degree of P limitation
853 within the region (P-replete: < 20% of the region is P-limited, Moderate: 20% -80%, Deplete: >
854 80%). The numbers next to the markers correspond to the months of the year. Contour lines show
855 C:P calculated under varying μ and $Chl:C_{phyto}$ with phytoplankton stoichiometry model under P-
856 limited condition.

857 **Figure 7:** Global climatology of average summer and winter CAFE-informed POC:POP (a-c) and
858 VGPM-informed POC:POP (d-f) in the surface mixed layer. Panels (g) and (h) show the range in
859 satellite-informed POC:POP, for summer and winter, respectively. Panel (i) shows the seasonal
860 change in median POC:POP.

861 **Figure 8:** Two graphical representation of the influence of $r_{C:P}$ and C_{phyto}:POC on bulk POC:POP. In
862 Panel (a), $r_{C:P}$ is plotted against POC:POP and contour lines show C_{phyto}:POC from 0 to 1. The
863 colored dots are annual mean CAFE-informed $r_{C:P}$ and POC:POP from the selected regions and the
864 grey dots in the background are monthly predictions from each 1° by 1° grid point. In Panel (b), $r_{C:P}$
865 is plotted against C_{phyto}:POC and the contour lines show POC:POP. Colored points represent

866   seasonally averaged POC:POP for four oceanographic regions, as in Figure 6. Both Panels (a) and (b)
867   highlight the importance of top-down control on POC:POP by C_{phyto}:POC.

868   **Figure 9:** Comparisons of modeled and observed zonal POC:POP for (a) summer and (b) winter. The
869   solid red curve shows the median POC:POP of the satellite-informed estimates, and shading shows
870   the range. The black dot in the box and whisker plot show the median POC:POP and the upper and
871   lower edges of each box correspond to the upper and lower quantiles. The vertical tails correspond to
872   a 95% confidence interval. When the sample size is 1, the sample variance could not be estimated,
873   and only the dot representing unique POC:POP is shown (e.g., 10°N during Summer). Note that the
874   satellite-informed POC:POP ratios are global latitudinal averages, whereas the measured POC:POP
875   are averages of discrete data points.

876   **Figure 10:** (a-b): Comparison of observed and modeled monthly C:P stoichiometry during 2003-
877   2010 in the surface 100 m for BATS and HOT. Solid black lines are 3-month running means, and
878   sample error bars are 1σ from the mean values. Solid blue and red lines are median estimates for
879   satellite-informed $r_{C:P}$ and POC:POP, respectively. The shadings show the range. (c-d): Box-whisker
880   plot comparing the annual ratios of satellite-informed phytoplankton C:P (blue), satellite-informed
881   POC:POP (red), and in-situ POC:POP (black). Each season represents a three-month average (Spring
882   = April to June, Summer = July to September, Fall = October to December, Winter: January to
883   March).
