Abstract

How to reveal the physical mechanism affecting the contact and friction behavior of geomaterials is still a challenging problem in predicting geological disasters, such as landslides and earthquakes. In this study, a multiscale friction model is developed to describe the microscopic creep behavior of asperities and the macroscopic sliding friction behavior of geomaterial. The theoretical asperities contact creep model can successfully capture the transition from the mechanical properties of microscopic asperities to the macroscopic interface friction-slip behavior by characterizing the

23   random contact process of the interface friction through porosity. This model also

24   verifies that the friction behavior of the geomaterials is strongly depends on their

25   temperature, activation energy, and saturation. Thus, the developed model can provide

26   a theoretical basis for a better understanding of the mechanical mechanism of the

27   contact and friction behavior in the geomaterials. Meanwhile, it would be of great help

28   in quantitatively predicting future geological disasters.

29

30   **Significance statement**

31   Friction was once old, is a new topic again. It is crucial in predicting catastrophic

32   geophysical risks. Thus, a physics-driven model of interfacial friction for geomaterials

33   is developed. This model characterizes the random contact process of the interface

34   through porosity, which successfully captures the transition of mechanical behavior

35   from microscopic asperities to the macroscopic friction interface. Meanwhile, our

36   model finds a close link between velocity-dependent friction versus geomaterial

37   properties and their stress states; and the velocity-dependent friction strengthening or

38   weakening effects are due to differences in directional and tangential activation energy.

39   The proposed mode offers a theoretical explanation for affecting the contact and friction

40   behavior of the geomaterials, which provides a theoretical basis for further prediction

41   of geological disasters.

42

43   ## 1. Introduction

44   In landslides and earthquakes, the geomaterials cause friction and slide due to

45   unbalanced forces, which can cause serious geological disasters. A description of the

46   interfacial friction behaviors of the geomaterials would be of considerable help in

47   predicting catastrophic failure progress. Considering that the geomaterials possess

48   porous randomness and multiphase heterogeneity, it remains challenging to

49   characterize the interfacial contact process and reveal the friction mechanism of the

50   geomaterials. Nowdays, the predictions of geological disasters mainly focus on

51   empirical or semi-empirical methods deriving from the various real-time monitoring

52   data on displacement and physical parameters of the geomaterials. However, the

53   prediction of geological failure progresses based on physical mechanisms is still an

54   urgent problem to be overcome.

55   Existing experimental studies focus on the relationship between the friction

56   behavior and sliding velocity of the fault geomaterials (Dieterich, 1978; Marone, 1998;

57   Tsutsumi and Shimamoto, 1997; Scholz and Engelder, 1976; Kilgore *et al.*, 1993), and

58   widely consider the effects of temperature and saturation (Scholz, 2019; Blanpied *et al.*,

59   1995; Blanpied *et al.*, 1998; Kubo and Katayama, 2015; Morrow *et al.*, 2000). Scholz

60   and Engelder (1976) reported a logarithmic velocity dependence of friction coefficient

61   in sliding experiments of granite. Then, Dieterich (1978) and Michael L. Blanpied et al.

62   (1998) observed similar phenomena on Wsterly granite. They pointed out that granite

63   had inherent velocity-dependent frictional weakening and temperature-dependent

64   frictional strengthening at all velocities. Also, the velocity-dependent frictional

65   weakening is very prevalent in rock avalanches (Hu et al., 2018; Wang et al., 2018; Hu

66   et al., 2022) and glacier avalanches (Iverson *et al.*, 2017; Thøgersen *et al.*, 2019; Gräff

and Walter, 2021), even some flow slides (Wang *et al.*, 2014; Pei *et al.*, 2017). In addition, velocity-dependent frictional strengthening has been observed in the clayed sliding zone of landslides (Wang *et al.*, 2010; Schulz and Wang, 2014; Miao and Wang, 2021). The velocity-dependent friction behavior controls the dynamics of faults and landslides on earth and other planets. These researches have provided new insights into the macro- or micro-mechanisms of the failure progress and velocity-dependent behaviors of geomaterials. Nevertheless, we know little about the underlying physics controlling the velocity-dependent friction behaviors of the geomaterials. Thus, it is urgent to establish a theoretical friction model based on the physical nature of the geomaterials.

Most experimental data-driven theoretical models are semi-empirical formulas lacking physical universality (Dieterich, 1979; Ruina, 1983; Scholz, 1998). Bowden and Tabor (B&T) considered the frictional strength of an interface as the product of an average velocity-dependent contact strength and the ratio of the actual contact area to the total contact area (Bowden and Tabor,1964; Berthoud *et al.*, 1999). The largely empirical rate-and-state (R/S) friction equations and Aging formulation (Dieterich, 1979; Dieterich, 1972) have been widely used to model time-varying friction phenomenology in rock (Marone, 1998; Dieterich, 1979; Beeler *et al.*, 1994) and a diverse set of industrial materials (Berthoud *et al.*, 1999; Prakash, 1998; Ronsin and Coeyrehourcq, 2001; Shroff *et al.*, 2014; Heslot *et al.*, 1994; Carlson and Batista, 1996). Einat Aharonov et al. (2018) developed a microphysics-based creep model, calculating the velocity and temperature dependence of contact stresses during sliding. Their model

4

89 also focused on the thermal effects of shear heating. Recently, Casper Pranger et al.

90 (2022) proposed transient viscous rheology that produces shear bands that closely

91 mimic the rate- and state- dependent sliding behavior of equivalent fault interfaces.

92   The above theories successfully explain the effect of sliding on friction, especially

93 in a high-velocity sliding state. Most models come from further developments of B&T

94 theory or R/S theory. However, these models are not deep enough to reveal the physical

95 nature of contact and friction behavior of geomaterials. Thus, some parameters of these

96 models remain empirically fitted. The above models do not consider how the

97 deformation of single contact asperities transitions to the entire contact surface because

98 they ignore the stochastic processes of contact and friction. The shear and normal stress

99 are the averages of a contact interface in the models. Moreover, some key influences,

100 such as porosity and permeability, on the friction behavior of geomaterials are still not

101 considered in these models. So, these empirically fitted models are limitations to predict

102 interfacial friction behaviors for geomaterials accurately.

103   On this basis, there is an urgent need to establish a physics-based interfacial

104 friction model coupling micro-contact to macro-friction, which further discloses the

105 effect mechanism of multi-physical factors on the friction behavior of geomaterials. In

106 this study, we develop a multiscale friction model that can describe microscopic contact

107 creep and macroscopic velocity-dependent friction. Then this model is explored to

108 examine the effects of slip velocity, temperature, porosity, and permeability on the

109 frictional behavior of geomaterials. Finally, the physical mechanisms of these

110 influences are discussed. Our model can elucidate the physics of interfacial friction for

111 geomaterials and has the potential to predict geological disaster progresses.

112

2. Theoretical model

114 The fiction behavior of geomaterials is considered to be the random and

115 continuous contact of microscopic asperities, resulting in the accumulation of contact

116 deformation and friction, which eventually develops into the sliding of the rough

117 contact surface. Therefore, the theoretical part includes the characterization of the

118 random contact process of the contact surface, the deformation mode of the contacting

119 asperities, and the friction-slip behavior of the rough contact surface.

2.1. Characterization of Random Contact Processes

121 Due to the porous nature of geomaterials, the porosity α is used to describe the

122 random contact process on rough surfaces, as shown in Fig. 1. Therefore, the contact

123 between two rough surfaces is considered as a process in which the pore volume is

124 continuously reduced and the real contact area is continuously increased until the

125 porosity is zero. The increase in the real contact area is caused by the continuous

126 increase of the contacting asperities, so a parameter γ is introduced to represent the

127 true contact ratio, which can be expressed as $\gamma = n / N_{\max}$, where n is the number of

128 asperities in contact, $N_{\max}$ is the number of contact asperities after full contact. The

129 porosity in initial contact is α_0, and the γ is considered to be zero at this time. As

130 contact occurs, α gradually decreases to 0, and γ gradually increases to 1.

131 Therefore, the relationship between α and γ can be described by an exponential

132 function

133
$$\gamma = \begin{cases} A^{\alpha}, \, 0 < A < 1, \, 0 \le \alpha < \alpha_0 \\ 0, \quad \alpha = \alpha_0 \end{cases}, \tag{1}$$

134 where, A is a fitting parameter that can be determined experimentally. The complex

135 random contact process is now characterized by a piecewise exponential function.

136

137 **2.2 Deformation and friction-slip behavior of the rough contact surface**

138   Sliding of geomaterials is a process of slow accumulation of internal contact and

139 friction, which is consistent with creep characteristics. Therefore, we still describe the

140 deformation of single contacting asperities based on the velocity creep theory proposed

141 by E. Aharonov and C H. Scholz (2018), as follows

142
$$\sigma_c = \sigma_c^0 [1 - b' \ln(1 + \frac{2r_0}{V t_c})], \tag{2}$$

143
$$\tau_c = \tau_c^* [1 + a' \ln(\frac{V}{V_{s\max}})], \tag{3}$$

144
$$T_c = T_0 + \frac{\tau_c}{\rho C} \sqrt{\frac{V}{\pi \beta}} [\sqrt{2r_0} + \frac{\sigma_n}{\sigma_c} \sqrt{D_{th}}], \tag{4}$$

145 where, σ_c and τ_c are normal and tangential stresses on the contact asperities

146 interface. T_c is the contact temperature. All parameters included in the equation are

147 shown in Table 1. Equations (2)-(4) illustrate that the deformation of contact asperities

148 is a creep process that is related to temperature, creep activation energy, and creep

149 velocity. Further, the frictional force between individual contacting asperities can be

150 expressed as $F_{si} = \tau_c S_{ri}$, where S_{ri} is the real contact area between individual

151 contacting asperities.

152   The pressure on single contacting asperities is certain, which satisfies

153    $\sigma_c S_{ri} = \sigma_n S_i$, where S_i is the nominal contact area of a single asperity and σ_n is the

154   normal stress acting on this nominal contact area. In addition, the sum of the nominal

155   contact areas ($N_{max} S_i$) of all contacting asperities is equal to the nominal contact area

156   (S_n) of the entire contact surface at the time of full contact, i.e., $N_{max} S_i = S_n$. Then,

157   F_{si} can be further expressed as

158
$$F_{si} = \tau_c S_{ri} = \tau_c S_i \frac{\sigma_n}{\sigma_c} = \frac{1}{N_{max}} S_n \sigma_n \frac{\tau_c}{\sigma_c}. \tag{5}$$

159   The frictional force F_s at the rough contact surface can be thought of as equal to the

160   sum of the shear forces of each asperity (nF_{si}), as follows

161
$$F_s = nF_{si} = \frac{n}{N_{max}} S_n \sigma_n \frac{\tau_c^*[1 + a' \ln(\frac{V}{V_{s\,max}})]}{\sigma_c^0[1 - b' \ln(1 + \frac{2r_0}{Vt_c})]} = A^\alpha S_n \sigma_n \frac{\tau_c^*[1 + a' \ln(\frac{V}{V_{s\,max}})]}{\sigma_c^0[1 - b' \ln(1 + \frac{2r_0}{Vt_c})]}. \tag{6}$$

162   The friction coefficient μ_s of the rough contact surface can be defined as the friction

163   force F_s divided by the positive pressure P i.e. $\mu_s = F_s / P$, where positive pressure

164   equals to $S_n \sigma_n$. Therefore, the μ_s can be expressed as

165
$$\mu_s = \frac{F_s}{P} = A^\alpha \frac{\tau_c^*[1 + a' \ln(\frac{V}{V_{s\,max}})]}{\sigma_c^0[1 - b' \ln(1 + \frac{2r_0}{Vt_c})]}. \tag{7}$$

166   Equation (7) includes porosity α, which is an inherent structural property of the

167   geomaterials. Their pores are closely related to the seepage coefficient and fluid

168   viscosity, which are important factors affecting the friction-slip behavior. Based on the

169   hydraulic diffusivity D_{hyd} ($D_{hyd} = \frac{k}{\eta m}$) (Wibberley, 2002) and the specific storage

170   capacity m ($m = \alpha(c_f + c_{pp})$) (Renner and Steeb, 2014), we can obtain the expression

8

171   for the porosity as follows

$$\alpha = \frac{k}{\eta(c_f + c_{pp})D_{hyd}}, \tag{8}$$

173   where, k is the permeability, η is the fluid viscosity, m is the specific storage capacity,

174   c_f is the compressibility of the pore fluid, and c_{pp} is the compressibility of the pore space.

175   Substituting equation (8) into equation (7), the friction coefficient can be expressed as

$$\mu_s = A^{\frac{k}{\eta(c_f + c_{pp})D_{hyd}}} \frac{\tau_c^*[1 + a'\ln(\frac{V}{V_{s\max}})]}{\sigma_c^0[1 - b'\ln(1 + \frac{2r_0}{Vt_c})]}. \tag{9}$$

177   Further, based on the relationship between permeability coefficient and saturation

178      $K = Le^{UW_S}$ (K: hydraulic conductivity; W_S: degree of saturation; L, U: fitting

179   parameters) (Li , 2021), the friction coefficient μ_s can be expressed as

$$\mu_s = A^{\frac{Le^{UW_S}}{\rho_f g(c_f + c_{pp})D_{hyd}}} \frac{\tau_c^*[1 + a'\ln(\frac{V}{V_{s\max}})]}{\sigma_c^0[1 - b'\ln(1 + \frac{2r_0}{Vt_c})]} \tag{10}$$

181   Equation (10) describes the friction coefficient of the macroscopic rough contact

182   surface, which is based on the creep accumulation of microscopic asperities and

183   includes random contact processes. Previous models considered the normal stress (or

184   shear stress) to be the same across the entire contact surface, which was an average

185   treatment. It should be noted especially that equation (10) only considers that the

186   deformation mode of each micro-contact asperity is the same, but the number of contact

187   asperities is random (in accordance with the exponential relationship), which is closer

188   to the real situation.

189

3. Experimental verification

To validate the proposed model, we compare with the results from high velocity-dependent ring shear tests of a loess landslide at different saturation (Pei *et al.*, 2017), as well as high velocity rotary shear frictional tests of familiar fault geomaterials concerning in quartz sandstone (Dieterich, 1978), granite (Dieterich, 1978; Di Toro *et al.*, 2004) , novaculite (Di Toro *et al.*, 2004; Di Toro *et al.*, 2011).

Figure 2 compares the predicted velocity effect results with the experimental results of loess at different saturation and fault geomaterials at different lithologies in a wide velocity range. The model well captures the velocity weakening effect at close saturation and saturation of loess materials. The experiment shows that for wet loess with saturation higher than 0.8 (0.83, 0.941 and 0.995), its velocity effect is obvious, which is well revealed by the proposed theoretical model (figure 2a). The dry loess, i.e., its saturation is zero, there is no observed velocity-dependent friction effects, and the proposed model can only predict its almost friction-constant behaviors at slide velocity lower 10^{-2} m/s (Figure 2a). The proposed model can also well predict the friction behavior of all compared fault geomaterials involving granite, quartz sandstone, and dense quartzite (Figure 2b). Generally, granite is denser with less porous than quartz and novaculite, which brings about different velocity effects for other fault geomaterials.

We also compare the results from Aharonov and Schol's model (Aharonov and Scholz, 2018), which employs the averaging stress at the contact surface. This means that the porosity of the geomaterial is zero, which does not exist in nature. However, the new model considers the influence of temperature and velocity for geomaterials

212 with different porosity (Figure 2c). It also precisely emerges the three modes and its

213 zones, i.e., no thermal effects, thermal effects, and melting, of contact temperature with

214 increasing slide velocity (Figure 2d). These have entirely consistent with Aharonov and

215 Schol's model (Aharonov and Scholz, 2018).

216 Therefore, the above results show the validity and correctness of the proposed

217 model. This also indicates that the contact temperature gradually increases until it

218 accumulates to a very high value during the slow sliding process (Zhang *et al.*, 2018).

219 The high temperature further causes the phase transition of the geomaterials, in turn

220 which results in a sharp decrease in the friction coefficient (Figure 2d). The coefficient

221 of friction decreases with increasing saturation in loess, as the water in the pores is

222 subject to pore pressure, which results in a lower friction due to the reduction of the

223 normal force between the contacting asperities. In addition, the liquid also has a

224 lubricating effect. Fault geomaterials with smaller pores have greater internal

225 friction, which means that the actual contact area of the contact surface is bigger thus

226 increasing the tangential force of the contact surface. Therefore, the coefficient of

227 friction decreases with increasing porosity (Figure 2c).

228

229 **4. Results**

230 **4.1 Effect of temperature**

231 The interface temperature of the geomaterial varies with the accumulation of the

232 creep process and the sliding velocity variation. This further affects the frictional

233 behavior of the geomaterial via changing its state. Figures 3 (a) and (b) show the friction

234 coefficient as a function of contact temperature. The friction coefficient gradually

235 decreases with the increase in contact temperature; meanwhile, it drops sharply when

236 the geomaterial reaches phase transition temperature (e.g. 1850ºC for loess and1670 ºC

237 for geomaterial).   This is because temperature affects the normal and tangential creep

238 processes, and has a more significant impact on the tangential direction once a

239 tangential slip occurs. Particularly, the tangential stress decreases with a faster speed

240 than the normal stress as contact temperature increases, causing a decrease in the

241 coefficient of friction. In addition, the geomaterials exhibit obvious flow characteristics

242 before the phase transition temperature.

243   Figures 3 (c) and (d) show the relationship between the ambient temperature and

244 friction coefficient of the loess and fault geomaterials under different sliding velocities.

245 The influence of ambient temperature on the friction coefficient is smaller than that of

246 the contact temperature because the maximum temperature difference between winter

247 and summer is only tens of degrees Fahrenheit. The ambient temperature change still

248 affects the creep stress in the normal and tangential directions of these geomaterials,

249 thus, the friction coefficient gradually decreases with the increase in temperature.

250

251 **4.2 Strengthening and weakening effects of friction**

252   Before the contact temperature reaches the phase transition temperature, the

253 friction coefficient will show different trends with the increase of sliding velocity, i.e.,

254 gradually decreasing (weakening effect), basically unchanged, and progressively

255 increasing (strengthening effect). This is since the difference between the creep

activation energy in the normal and tangential directions of the geomaterial.

This difference indicates the relative ease with which creep occurs in the normal and tangential directions. When the difference between the activation energy of tangential and normal creep is small, the friction coefficient is a very slight change with the slow increase of the sliding velocity. This means that the tangential and normal creep processes are similar in difficulty, resulting in almost constant friction coefficient, as shown in Figure 4.

When the creep activation energy in the normal direction of the asperities is smaller than that in the tangential direction, the friction coefficient decreases gradually with the slow increase of the sliding velocity (Figure 4). This is because normal creep is more likely to occur, and the normal stress reduction is smaller than the tangential stress reduction. As a result, the friction coefficient decreases. Similarly, when the creep activation energy in the normal direction of the asperities is greater than that in the tangential direction, the friction coefficient gradually increases with the slow increase of the sliding velocity (Figure 4). This is because tangential creep is more likely to occur and the tangential stress reduction is smaller than the normal stress reduction, causing an increase in the coefficient of friction.

The creep activation energy of geomaterials is closely related to the properties, composition, and other factors of these geomaterials. Therefore, different materials will show shear strengthening or weakening, even constant shear strength with increasing slide velocity.

4.3. The effect of permeability and viscosity

The permeability coefficient and liquid viscosity can significantly affect the frictional behavior of geomaterials as they determine water distribution and flow characteristics in geological disasters.

Figure 5 shows the effect of permeability coefficient and fluid viscosity on friction coefficient at different velocities. The coefficient of friction decreases as the permeability coefficient increases. This is because the larger permeability makes the water flow more easily and widely in granular materials, such as loess, which enhances the lubrication effect and reduces the force between asperities. Similarly, fluid viscosity can hinder its flow and widespread distribution in granular materials. Therefore, the coefficient of friction increases with the coefficient of fluid viscosity.

The above results elucidate that the macroscopic contact and friction behavior of the geomaterials depend on the creep accumulation process of microscopic asperities in the normal and tangential directions. This is closely related to temperature and creep activation energy. However, temperature-induced changes in normal and tangential stresses and phase transitions significantly affect the changes in its frictional force. The relative creep difference in the normal and tangential directions of the asperities can cause velocity strengthening or weakening effects. It is due to the different amounts of stress reduction in the tangential and normal directions corresponding to different activation energies. In addition, the water content also significantly affects its friction coefficient, which can attribute to the lubrication effect and the role of sharing part of the pore pressure. Thus, the permeability and fluid viscosity coefficients, which affect

the water flow and distribution characteristics, affect the coefficient of friction.

5. Conclusion

Based on frictional contact theory, a physics-driven model of interfacial friction is built for geomaterials. Our theoretical model characterizes the random contact process of the interface through porosity, which successfully captures the transition of mechanical behavior from microscopic asperities to the macroscopic friction interface. The theory reveals the velocity-dependent sliding friction behavior of these verified geomaterials and shows that the interparticle contact temperature has a more dominant role in velocity-dependent friction than the ambient temperature. The velocity-dependent friction behavior can attribute to the adjustment of stress state and property during high-velocity shearing. Meanwhile, the difference in directional and tangential activation energy can cause velocity-enhancing or weakening effects for geomaterials. The saturation of geomaterials not only exhibits the lubrication effect but also shares part of the pore pressure, which contribute to the decrease in the friction coefficient. Thus, the permeability and fluid viscosity coefficients, which affect the water flow and distribution characteristics, also affect the coefficient of friction. These findings provide a further understanding of the physical mechanism how shear velocity affect the contact and sliding friction of geomaterials. It has important implications for geological hazard prediction, not only in landslides and earthquakes but also in glacial avalanches on earth, even slide failure progresses on other planets.

454 **Figures**

455

456 **Figure 1**. Illustration of the profile of shearing contact rough surface and single contacted asperities.

457 The blue region depicts a highly compressed area that experience internal creep driven by normal

458 stress, with the maximum compressed region is represented by purple. The gray area contains

459 localized shear-activated creep.
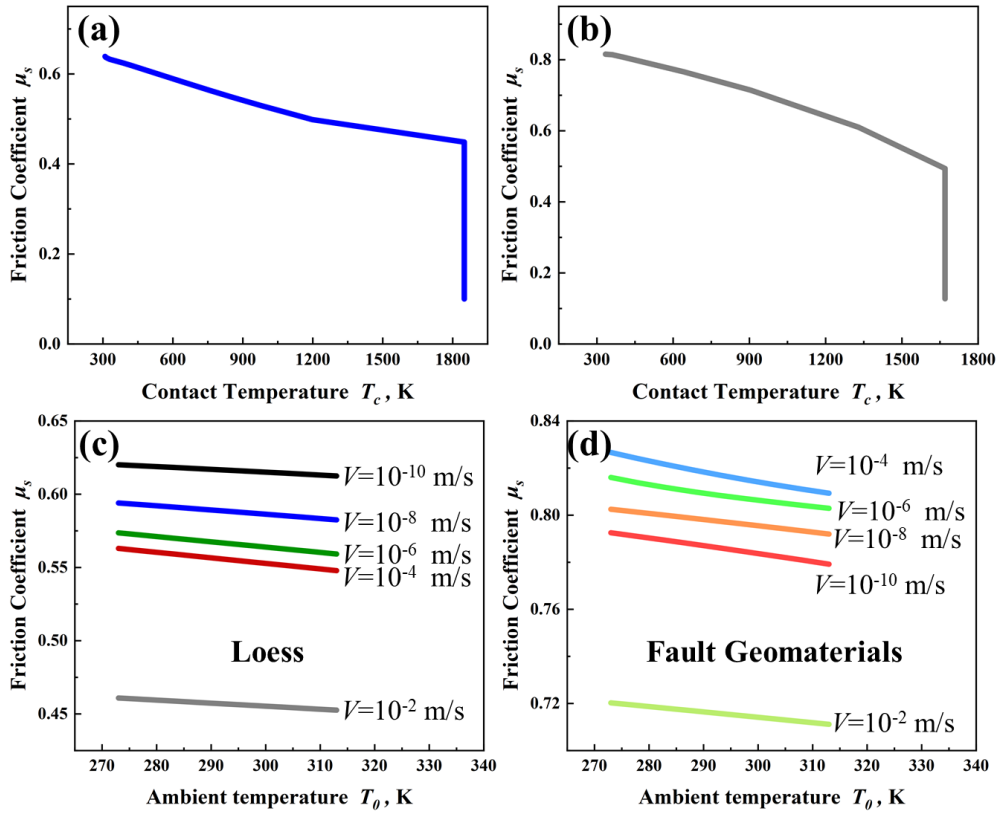

460
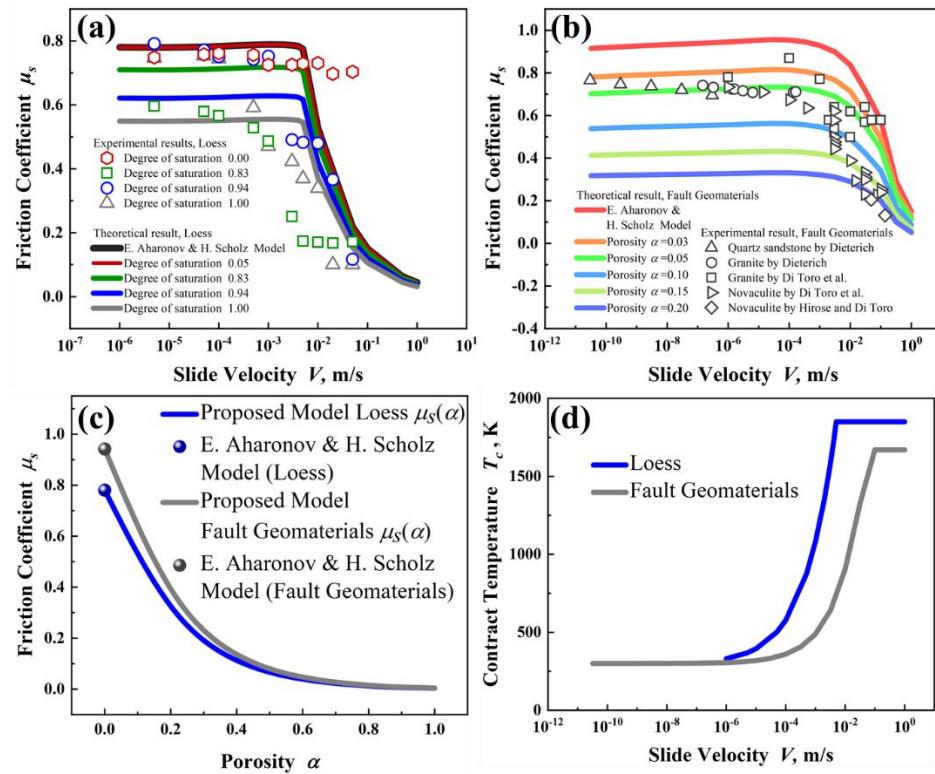

Figure 2. The comparison of the prediction results of the proposed model with the experimental results of loess (a) and fault geomaterials (b). (c) Coefficient of friction as a function of porosity. (d) The relationship between the contact temperature of the contact surface of the geomaterial and the sliding velocity.

461

462

463

464

465

468   **Figure 3**. (a) The relationship between the contact temperature of the contact surface and friction

469   coefficient of the loess. (b) The relationship between the contact temperature of the contact surface
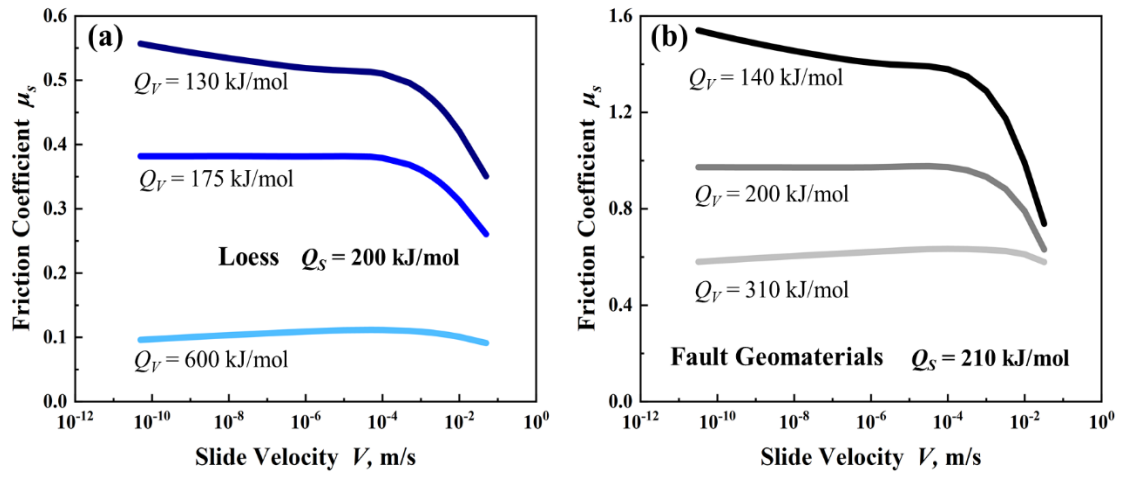

470   and friction coefficient of the fault geomaterial. (c) The relationship between the ambient

471   temperature and friction coefficient of the loess under different sliding velocities. (d) The

472   relationship between the ambient temperature and friction coefficient of the fault geomaterial under
473   different sliding velocities.

474

Figure 4. (a) Effect of creep activation energy difference on friction coefficient of loess. (b) Effect

of creep activation energy difference on friction coefficient of fault geomaterial.

478

479

480 **Figure 5**. (a) Effect of permeability on friction coefficient of loess. (b) Effect of fluid viscosity on

481 friction coefficient of loess.

483

Table 1. Table of Parameters, Definitions, and Values

Parameters	Value (Quartz)	Value (Loess)
σ_n^0	$\sigma_c^{\ 0} = \dfrac{Q_V B}{N_A \Omega_v}$	N_A is the Avogadro number
τ_c^*	$\tau_c^{\ *} = \dfrac{Q_S}{N_A \Omega_S}$	N_A is the Avogadro number
a'	$a' = \dfrac{RT_c}{Q_S}$	R is the Gas constant
b'	$b' = \dfrac{RT_c}{Q_V B}$	R is the Gas constant
Q_S (KJ/mol) Surface activation energy	210	660
Q_V (KJ/mol) Volume activation energy	240	400
Ω_S (10^{-29}m³) Surface activation volume	6.00	3.10
Ω_V (10^{-29}m³) Volume activation volume	6.80	1.40
B Prefactor	0.8	0.9
r_0 (mm) Contact radius	5	5
t_c (s) Cutoff time	$t_c = t_{cr} \dfrac{T_c}{T_{cr}} \exp(-\dfrac{E_{tc}}{RT_c} \dfrac{\Delta T_c}{T_{cr}})$	$t_c = t_{cr} \dfrac{T_c}{T_{cr}} \exp(-\dfrac{E_{tc}}{RT_c} \dfrac{\Delta T_c}{T_{cr}})$
t_{cr} (s) Reference cutoff time	2	2
T_{cr} (K) Reference temperature	300	300
E_{tc} (KJ/mol) Activation energy for t_c	$E_{tc} = (1-B)Q_V$	$E_{tc} = (1-B)Q_V$
V_{smax} (m/s) Maximum shear rate	1875	200
T_0 (K) Ambient temperature	300	300
C (J/kg/K) Specific Heat Capacity	730*(170-200/T_c)	3000-(300000/T_c)

β (m²/s) Thermal diffusivity	$\beta_0 \times 10^{-4}/T_c - 0.5 \times 10^{-7}$	$\lambda/(\rho \cdot C)$
β_0 (m²/s) Thermal diffusivity	2.5	-
ρ (kg/m³) Density	2650	1400
λ (W/m/K) Heat transfer rate	-	1.2
D_{th} Thermal equilibration distance	$D_{th} = k\sigma_n^{\,q}$ here assume $k = 5, q = -1$.	$D_{th} = k\sigma_n^{\,q}$ here assume $k = 5, q = -1$.
σ_n (MPa) Applied normal stress	5	0.2
T_m (K) (Pre) melting temperature	1670	1850
A	0.005	0.005, 0.0005, 0.03, 0.4
D_{hyd} (m²/s) Hydraulic diffusivity	-	0.0008
c_f (kPa^{-1}) Compressibility of the pore space	-	-
c_{pp} (kPa^{-1}) Compressibility of the pore fluid	-	-
$c_{pp} + c_f$ (kPa^{-1})		3×10^{-7}
η (Pa·s) Fluid viscosity	-	$3 \times 10^{-4} \sim 1.8 \times 10^{-3}$
k (m²) Permeability	-	$1 \times 10^{-14} \sim 1 \times 10^{-10}$
K (m/s) Hydraulic conductivity	-	$K = Le^{UW_s}$ $E = 2.172 \times 10^{-8}, F = 10.55$
