12 **Key Points:**

- 13 • Accurate bathymetries (<1 m) in forereef wave energy dissipation models highlight
14 previously overlooked features of the forereef, including spurs and grooves (SaG).
- 15 • SaG influence forereef wave energy dissipation and this influence can be related to the
16 SaG morphology.
- 17 • Future climate change projections modify dissipation rates by shifting the dominant
18 mode of dissipation (from bed friction to wave breaking) leading to an increase wave
19 overtopping on forereefs.

20

21 **Abstract**

22 Coral reefs protect coastlines from inundation and flooding, servicing over 200 million people
23 globally. Wave transformation has previously been studied on coral reef flats with limited focus on
24 forereef zones where wave transformation is greatest during high-energy conditions. This study
25 investigates the role of forereef spur and groove (SaG) morphology on wave energy dissipation and
26 overtopping on coral reefs. Using XBeach on LiDAR-derived bathymetry, we reproduced dissipation
27 rates comparable to SaG field studies under present-day conditions. Our results highlight the
28 benefits of accurate bathymetries in forereef wave energy dissipation models, as they incorporate
29 critical morphological features (e.g., groove sinuosity, irregular forereef slopes) that exert control
30 over mode of wave energy dissipation (frictional and breaking). We then investigated changes to
31 wave energy dissipation and wave overtopping based on IPCC AR5 low and high emission scenarios

32 (RCP2.6 and RCP8.5) and a total disaster scenario (TD) for the year 2100 considering changes to SaG
33 morphology, wave power and relative sea-level rise. For RCP2.6, an increase in wave heights of 0.8
34 m and an increase in water level of 0.3 m resulted in a two-fold increase in dissipation rates. For
35 RCP8.5 and TD, with no increase in incident wave height, dissipation rates were 29% and 395% lower
36 than RCP2.6. This resulted in increased overtopping at the reef crest by 1.8 m and 2.7 m for RCP8.5
37 and TD scenarios, respectively, when compared to RCP2.6. Decreased dissipation rates and
38 increased wave overtopping in forecasted climate conditions suggest the need for strategies to
39 promote coral growth to facilitate high dissipation rates in the future. The results from our novel
40 modelling approach have implications for the future habitability of exposed reef-lined coasts due to
41 increased exposure to coastal flooding and island inundation.

42 Plain language summary

43 Coral reefs are essential for protecting coastlines from floods and waves, benefiting over 200 million
44 people worldwide. We studied how waves change as they approach coral reefs, focusing on the
45 forereef zone where wave transformation is most significant during high-energy conditions. The
46 shape of the forereef, specifically the spur and groove (SaG) morphology, plays a crucial role in how
47 much wave energy is dissipated and how much water spills over the reef.

48 Using a digital representation of waves over accurate reef shapes (known as bathymetry), we
49 simulated wave dissipation rates comparable to real-world SaG studies. Our findings emphasize the
50 importance of accurate representations of forereef shapes in models to predict wave energy
51 dissipation, as they consider critical features such as SaG which affect how waves transform and lose
52 energy.

53 Next, we investigated how wave energy dissipation and overtopping might change under different
54 future climate scenarios. We considered low and high emission scenarios (RCP2.6 and RCP8.5) from
55 the IPCC AR5 report and a total disaster scenario (TD) for the year 2100, factoring in changes to
56 forereef elevation, wave power, and sea-level rise.

57 Under the low emission scenario (RCP2.6), with a slight increase in wave heights and water levels,
58 we observed a doubling of wave energy dissipation rates. However, under the high emission
59 scenario (RCP8.5) and the total disaster scenario (TD), dissipation rates decreased significantly
60 compared to RCP2.6, resulting in more water moving over the reef crest during storms. This suggests
61 that future climate conditions may lead to increased flooding and inundation on reef-lined coasts,
62 putting communities at risk.

63 In summary, our study highlights the benefits of using accurate reef shapes in simulating wave
64 energy dissipation on coral reefs. Accurate bathymetries can incorporate features such as spurs and
65 grooves of different shapes, which modify wave dissipation. Wave energy dissipation changes when
66 climate change projections are incorporated into the simulations leading to an increase in energy
67 passing over the forereef.

68 1. Introduction

69 Coral reefs provide many ecosystem services including coastal hazard protection from ocean waves,
70 with over 200 million people worldwide depending on the stability of this service (Ferrario et al.,
71 2014). Coral reefs are topographically complex structures which contribute to the frictional
72 dissipation of waves, however this has been studied in greater details on the reef crest and reef flat
73 (Ferrario et al., 2014; Monismith et al., 2015; Péquignet et al., 2014; Yao et al., 2020) than on the
74 high-energy environments of the forereef slope (Acevedo-Ramirez et al., 2021; Duce et al., 2014,
75 2016, 2022; Monismith et al., 2013; Sheppard, 1981). Yet, wave breaking on the forereef slope is the
76 dominant form of wave energy dissipation under high-energy conditions (Osorio-Cano et al. 2018)
77 suggesting that it is a critical region for coastal protection (Quataert et al. 2015a). High dissipation
78 rates on the forereef are controlled by forereef morphology such as spurs and grooves (SaG)
79 (Monismith et al., 2013; Osorio-Cano et al. 2018).

80 SaG are shore-normal elongate ridges (spur) and troughs (groove) on the foreereef slopes of many
81 coral reefs (Duce et al., 2016). Their size, spacing and orientation are typically aligned with incident
82 waves and consequently the morphometric classification of SaG (Duce et al., 2016) reflects the
83 influence of waves in their formation (Table 1). High energy foreereefs feature more defined SaG than
84 low-energy ones (Duce et al., 2016; Rogers et al., 2013). Recent research shows high-relief (up to 10
85 m) spurs in the Mexican Caribbean have a large influence over wave transformation, with dissipation
86 in the SaG zone contributing a 35% in wave energy flux. Wave energy flux on the foreereef occurs
87 mostly in the sea-swell frequency band (> 0.04 Hz). While infragravity waves (0.004-0.04 Hz) are
88 important to wave transformation over reef flats and in lagoons (Cheriton et al. 2016), field
89 measurements of waves over SaG have shown negligible energy in the infragravity bands (Duce et al.
90 2022). A recent investigation into SaG morphology demonstrates that SaG are not optimised to
91 maximise wave energy dissipation, with their morphology dissipating energy while allowing energy
92 propagation (and water, nutrients, and oxygen) to facilitate coral growth in the lagoon (Johannsen et
93 al., in review). Further field investigations are required but have been limited by the difficulty of
94 accessing highly exposed and turbulent foreereef slopes (Sheppard 1981; Sous et al. 2022).

95 SaG morphologies have been overlooked in both physical (e.g., Buckley et al., 2016) and numerical
96 models (e.g. Baldock et al., 2020; Monismith et al., 2013; Osorio-Cano et al., 2018) of foreereef wave
97 attenuation. For instance, numerical models that include SaG morphologies typically use idealised
98 bathymetries (e.g. da Silva et al., 2020; Rogers et al., 2013) with simplified morphologies that
99 overlook the irregularity and diversity of SaG. Consequently, the impact of SaG morphologies (Table
100 1) on wave attenuation is poorly understood (Duce et al., 2022; Monismith et al., 2013; da Silva et
101 al., 2020).

102 Table 1: Morphological categorisation of SaG (Duce et al., 2016).

Deep and Disconnected (DaD)	Grooves are disconnected from the reef crest and appear in deeper water (>5.5m) with limited hydrodynamic energy
Exposed to wave energy (EWE)	This morphology is heavily governed by the wave climate. Grooves are oriented perpendicular to incoming wave crests.
Log and protected (LaP)	Grooves are longer (>50m) and wider than more exposed grooves
Short and protected (SaP)	These grooves are narrower and shorter than Class 3.

103

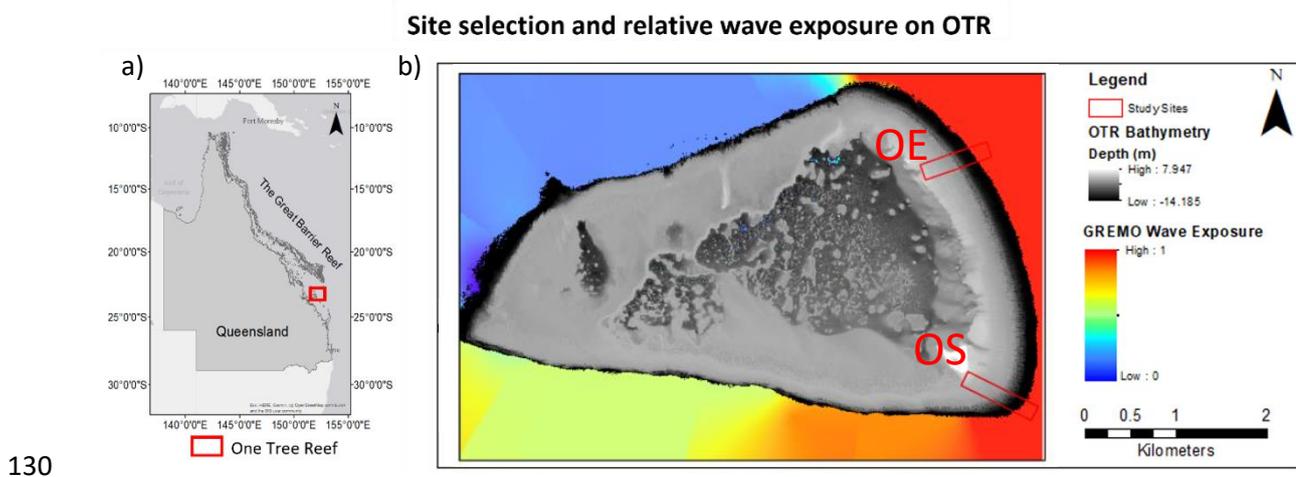

104 Studies have shown that forereef morphologies including SaG will be impacted by climate change
 105 (Castillo et al., 2012; De'Ath et al., 2012; Hughes et al., 2018) likely resulting in reduced coastal
 106 protection (Baldock et al., 2014; Ferrario et al., 2014; Quataert et al., 2015; Sheppard et al., 2005)
 107 and increased wave overtopping (Amores et al. 2022; Beetham and Kench 2018). Most notably, a
 108 loss of structural complexity (roughness) in forereefs will reduce bed friction impacting wave
 109 attenuation (Baldock et al., 2014; Harris et al., 2018; Monismith et al., 2015; Rogers et al., 2016).
 110 These impacts are exacerbated by relative sea-level rise, changes in regional wave power (Meucci et
 111 al., 2020; Reguero et al., 2019) and modification and intensification of storm climates (Knutson et al.,
 112 2015) which all modify wave transformation processes on forereefs.

113 The overall aim of this paper is to provide understanding of present day and forecasted wave
 114 attenuation by SaG on coral reefs. Both of which are critical for coral reef management plans and
 115 climate change adaptation strategies. To achieve this, we first identify the benefits of high-resolution
 116 LiDAR-derived bathymetries in numerical wave models. Then we employ these models to determine
 117 how SaG of different morphological class affect the dissipation of wave energy. Finally, we
 118 investigate the effects of climate change on wave energy dissipation over SaG.

119 2. Methods

120 2.1 Study Site

121 One Tree Reef (OTR) (23°30'S, 152°06'E) is located 84 km offshore of the NE Australian mainland in
 122 the Capricorn Bunker Group, in the southern Great Barrier Reef (GBR) (Figure 1a). OTR is a lagoonal
 123 platform reef with semi-diurnal tides with a mean spring tidal range of 3 m. The entire forereef of
 124 OTR features SaG (Duce et al., 2016). The mean significant offshore wave height, $H_{s,mean}$ of 1.7 m
 125 (Smith et al., 2022) is typically generated from persistent SE trade winds that dominate the Coral Sea
 126 for over 70% of the year (Jell and Webb, 2012). Consequently, the south-eastern forereef is the most
 127 exposed to ocean swells (Figure 1b). We considered two study sites featuring SaGs of varying
 128 morphological class (Table 1) on the eastern and southern side of OTR (henceforth labelled OE and
 129 OS respectively) (Figure 1b, Table 1).

131 *Figure 1: a) One Tree Reef (OTR) in the Southern Great Barrier Reef, and b) Study site locations for*
 132 *OTR East (OE) and OTR South (OS) and relative wave exposure (Pepper and Puotinen 2009).*

133 2.2 SaG morphometric analysis

134 We determined morphometric parameters for SAG in the two study sites including length, depth,
 135 width, and others (Table 2) from analysis of LiDAR derived bathymetry and used them to classify the
 136 SAG following the categorical framework of Duce et al. (2016) (Table 1).

137 Table 2: Morphometric parameters of SaG adapted from Duce et al. (2016).

Morphometric parameter	Method
Length (L)	Path distance along the groove (m)
Depth (D)	The vertical distance between the lowest point in the groove and the highest point on the neighbouring spur is calculated at four depths below sea level (-2, -4, -6, and -8 meters).
Width (W)	Groove width is measured as the horizontal distance between its walls at half the depth, along isobaths of -2, -4, -6 and -8 m.
Orientation (θ)	Azimuth of straight line between maximum onshore and offshore extents of groove
Sinuosity (S)	Ratio of straight-line distance (D) to path length (L) such that: $S = D/L$
Wavelength (γ_{saG})	The horizontal distance between the highest points of adjacent ridges, parallel to isobaths, measured at depths of -2, -4, -6, and -8 meters below mean sea level.

138

139 **2.3. Wave transformation modelling (XBeach)**

140 We used XBeach (Roelvink et al., 2015) in Surf Beat mode to understand hydrodynamics and wave
 141 attenuation over SaG because it has been extensively validated on complex coral reef bathymetries
 142 (Harris et al., 2018; Lashley et al., 2018; Quataert et al., 2015, 2020; da Silva et al., 2020).

143 **2.3.1 Bathymetric Grids**

144 We merged data from a 0.5 m resolution Airborne LiDAR survey (Harris et al., 2023) to a depth of 14
 145 m, and a 30 m resolution bathymetry survey (Beaman, 2017) to a maximum depth of 20 m (Figure
 146 2). This maximum depth was selected to capture all depth-limited wave breaking within the model
 147 and was based on historical wave heights for OTR considering,

148

$$H_{max} = \gamma \cdot (h + \delta H_{rms})$$

149

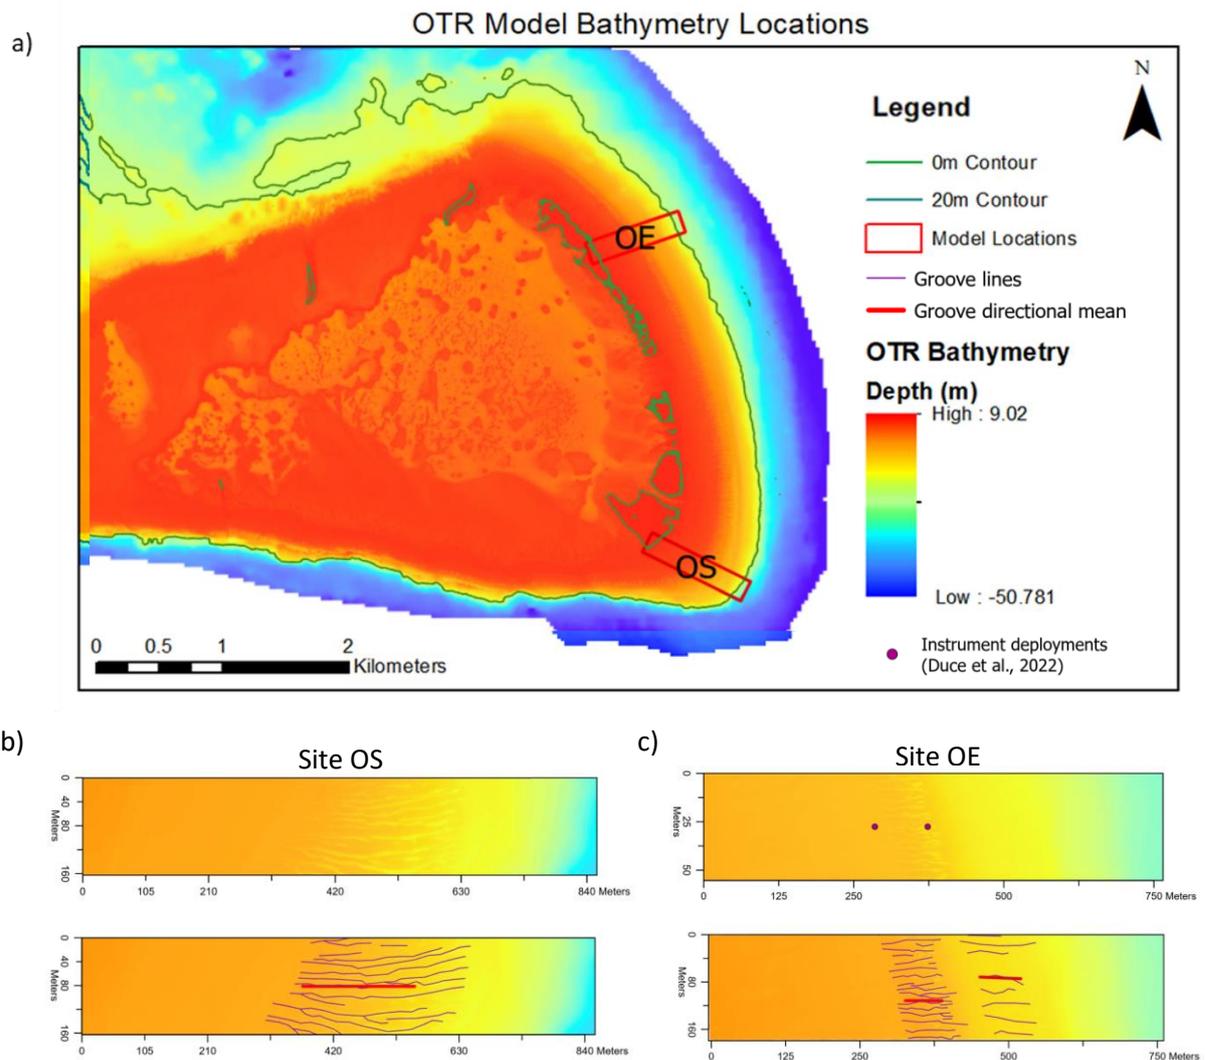

where, γ is the breaker index, δH_{rms} is some fraction δ of the root mean square of the wave height.

150

The breaker index was held constant across the reef at $\gamma = 0.55$, reflecting the conservative

151

estimation ($\gamma = 0.55$) of (Duce et al., 2022) and within the ranges determined by Harris et al. (2018).

152

153 *Figure 2: a) The bathymetric grids used in wave models from two study sites on the eastern (OE) and*

154

southern (OS) exposed forereefs of on One Tree Island. Grooves are shown in purple with the

155

directional mean of SaG shown in red.

156

The outer boundaries of the bathymetric grids were oriented to align mean groove headings with

157

incident waves (Figure 2b and c), following field observations (Duce et al., 2014; Munk and Sargent,

158 1948; Shinn, 1963) and other wave transformation models constructed over SaG (Rogers et al., 2013;
159 da Silva et al., 2020) (Figure 2b). Offshore boundaries were set beyond the maximum breaker depth
160 for modelled wave heights (20 m: Eq. 1) and the onshore boundaries at present-day 0 m MSL
161 contour (Figure 2b, c). Consequently, grids for each site are of different length and width (Figure 2b).

162 2.3.2 Climate change projections

163 We considered four climate change scenarios projected for the year 2100 including critical climate
164 impacts to wave energy dissipation on coral reefs: sea-level change, reef health and wave energy
165 conditions. The climate change scenarios are based on IPCC AR5 and include (1) the *present-day*
166 scenario considering no change to current environmental factors, (2) the *low* (RCP 2.6) and (3) *high*
167 (RCP8.5) emission scenarios from the AR5 IPCC report (Shukla et al., 2019), and (4) a *total disaster*
168 (TD) scenario included to represent a high carbon future.

169 2.3.2.1 Changes to Sea Level

170 We used IPCC AR5 sea-level rise (SLR) rate of 3 mm/yr (Shukla et al., 2019). Under the *low* and *high*
171 emission scenarios (RCP2.6 and RCP8.5) SLR is expected to reach up to 10-20 mm/yr. Subsequently,
172 we have included SLR of 0.43 m (RCP2.6) and 0.84 m (RCP8.5) for the year 2100 (Shukla et al., 2019).
173 Human stressors (e.g., infrastructure development and human-induced habitat degradation) are also
174 likely to contribute to increases in local SLR (Shukla et al., 2019). An additional 1 m of eustatic SLR
175 was included for our *total disaster* (TD) scenario to reflect significant changes to climate conditions
176 and non-climatic anthropogenic stressors (Shukla et al., 2019) (Table 3). The total sea-level increase
177 in each of the models (Table 3) was determined by the sum of eustatic and local sea-level changes,
178 and the vertical accretion and erosion of the reefs.

179 2.3.2.2 Reef Morphological Changes

180 Reef morphological changes have been simplified into three key characteristics, reef vertical
181 accretion, erosion, and structural complexity. A forecasted vertical accretion rate of 2 mm/yr was
182 used based on field measurements from coral reef cores from across the GBR (Dechnik et al., 2015;
183 Sanborn et al., 2020), Western Australia (Perry et al., 2018), Tahiti (Buddemeier and Smith, 1988),

184 the Maldives (Kench et al., 2022), Indo-Pacific averages compiled by Montaggioni (2005) and the
 185 Solomon Islands (Saunders et al., 2016). Alternatively, erosion of forereefs can occur due to the
 186 physical removal of coral and framework by storms and high wave energy (Madin and Connolly,
 187 2006). This is most evident on degraded coral reefs where erosion has been observed at 6 mm/yr
 188 (Eakin, 1996; Sheppard et al., 2005). We used a conservative estimate of 2.6 mm/yr (0.2 m by 2100)
 189 of reef erosion for RCP 8.5 and a maximum of 6.4 mm/yr (0.5 m by 2100) of erosion under a TD
 190 scenario, modelled as a uniform decrease in elevation over the simulated domain. The resulting sea
 191 level was determined by combining projected rates of SLR with erosion and accretion values for each
 192 scenario (Table 3).

193 To simulate a loss in forereef structural complexity, we altered the dimensionless wave friction
 194 factor (f_w) to replicate changes to coral structural complexity. In our study, f_w were linearly
 195 interpolated between $f_w = 0.9$ (healthy reef) to $f_w = 0.1$ (degraded or smoothed reef). For the *total*
 196 *disaster* (TD) scenario, which represents a degraded reef and a shift to a carbonate sand substrate
 197 we used $f_w = 0.01$ (Smyth and Hay, 2002) (Table 3).

198 2.3.3 Wave Input Parameters

199 Mean offshore wave conditions were determined by satellite altimeter observations over 30 years
 200 (1985–2015) using RADWave (Smith et al., 2020) (Table 3). A small region (0.6° x 0.4°) representing
 201 dense altimeter data tracks was identified on the eastern, exposed side of OTR (Figure S1). We
 202 determined site-specific model input wave heights (H_{model}) by combining offshore wave conditions
 203 with a relative wave exposure model, GREMO (GIS-based generic model for estimating relative wave
 204 exposure; see Figure 1b) following Pepper and Puotinen (2009),

$$205 \quad H_{model} = K_r H_{offshore} \quad (1)$$

206 where, $H_{offshore}$ is the offshore wave height obtained from RADWave (Figure 1b and Figure S1) and
 207 K_r is the relative exposure coefficient, normalised between 1 (most exposed) and 0 (least exposed).

208 Finally, altimeter wave heights were compared to measured waves at the northern forereef at OTR
 209 (Duce et al., 2022).

210 2.3.4 Changes to wave climate

211 We increased offshore model wave heights (H_{offshore}) for future climate change scenarios (Table 3)
 212 with wave periods (T_{model}) determined for a fully developed sea-state from the Joint North Sea Wave
 213 Project (JONSWAP) spectrum (Young, 1992). Storm waves were calculated from the maximum wave
 214 height observed in RADWave altimeter data. The final model wave heights were dependent on
 215 forereef location and relative exposure to wave energy determined by Eq. 1.

216 *Table 3: Model input parameters are presented for three study sites, two wave conditions and four*
 217 *forecasted climate outcomes for the year 2100. A total of 16 unique models were run.*

Site	Climate scenario	Wave Condition	H_{offshore} (m)	Exposure Factor	H model (m)	T_{model} (s)	Friction factor	SLR (m)	Vertical Accretion (m)	Reef erosion (m)	Total change in MSL (m)							
OS	Present day	Mean	1.34	0.985	1.3	5.74	0.9	0	0	0	0

218

219 2.3.5 XBeach model outputs

220 Each model was run for a total of 300 seconds, and we analysed the outputs of Xbeach for water
 221 surface elevation (z_s), total dissipation rate (D), and dissipation rate due to bed friction (D_f) to
 222 obtain wave energy dissipation rates and wave overtopping. Total dissipation was used to compare
 223 Xbeach results with field measurements and to determine dissipation by breaking (D_b) such that
 224 $D_b = D - D_f$. As models are two-dimensional (x, y spatial domains) and evolve through time (t), we
 225 calculated mean and peak dissipation rates across t and x domains for the entire bathymetric grid.
 226 Mean dissipation rates were also taken between two points where hydrodynamic data sampled by
 227 Duce et al. (2022). Wave overtopping was calculated as the difference between the initial water level
 228 at the reef crest and the maximum water level at the reef crest during each model run.

229 3. Results

230 3.1 SaG morphometric analysis

231 SaG morphometrics were quantified for 123 grooves across the two study sites (Table 3). Grooves at
 232 the southern site (OS) were on average 3 times longer, 1.4 times deeper and 1.3 times wider than
 233 those at the eastern site (OE) (Table 3). Using the morphometric classification of Duce et al. (2016),
 234 the exposed to wave energy (EWE) grooves were the most common across three of the four sites
 235 (100 of 123 SaG) (Table 3). Deep and disconnected (DaD) grooves were present on the lower
 236 forereef platform of site OE.

237 *Table 4: Morphometric parameters and classes of SaG at two study sites.*

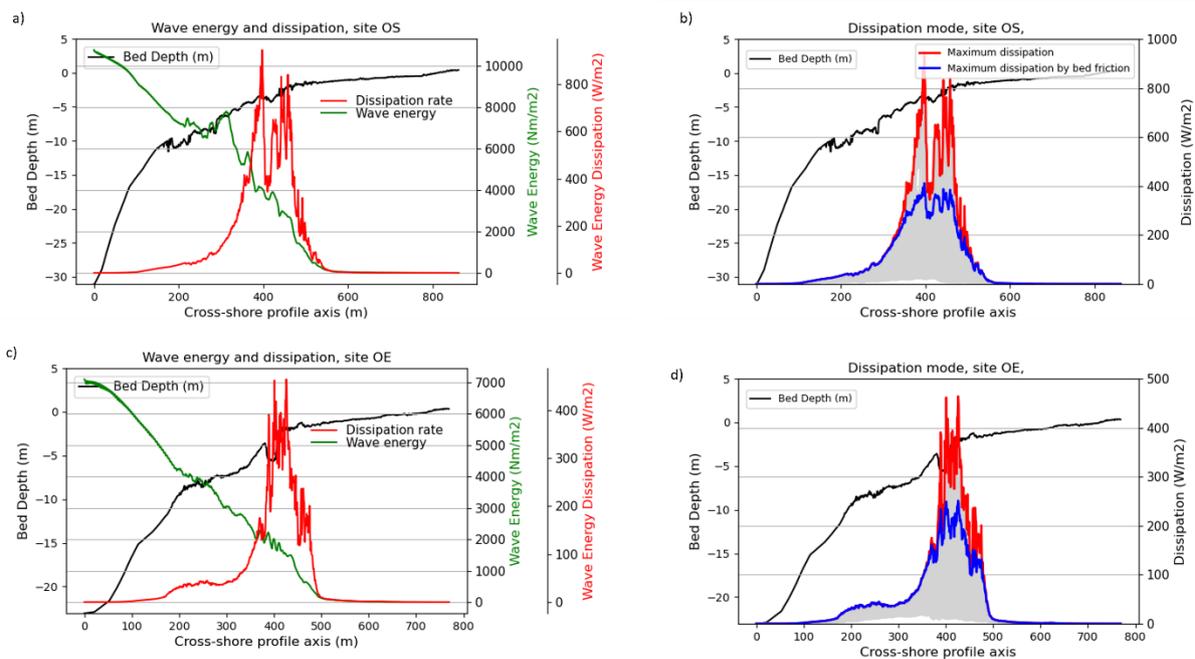

Site	Mean SaG Morphometric Parameters					Quantity of SaG Classes by Site			
	Length (m)	Sinuosity	Orientation (Deg)	Depth (m)	Width (m)	DaD	EWE	LaP	SaP

OS	187.12	0.99	116.73	1.95	4.02	0	40	0	0
(south)									
OE	63.18	0.99	71.5	1.38	3.12	23	60	0	0
(east)									

238

239 **3.2 Wave transformation over LiDAR derived bathymetry**

240 The peak dissipation rates under present day conditions, taken as the maximum dissipation across
 241 all axes (x, y, t), were 463.9 and 946.3 W/m² at sites OE and OS respectively (Figure 4). Wave energy
 242 dissipation due to bed friction was dominant in present day scenarios over dissipation due to wave
 243 breaking (Figure 4b and d). Between the two locations of field measurements conducted by Duce et
 244 al., (2022) (Figure 2c) the mean dissipation rate was 10.6 W/m², the maximum dissipation rate of
 245 463.9 W/m² occurred during this zone. Wave energy dissipation by bed friction contributed 78% of
 246 energy at the site OE before waves reached the reef crest, 67% at site OS in the upper foreereef
 247 slope. The maximum wave energy dissipation due to wave breaking constituted 22%, and 32% of
 248 total dissipation at site OE and OS respectively (Figure 4b, d).

249

250 *Figure 4: Wave energy (green) and maximum wave energy dissipation at site OS (a) and site OE (c).*
251 *Maximum dissipation and maximum dissipation by bed friction (blue) for site OS (b) and site OE (d).*
252 *Note different scale bars are used for each site.*

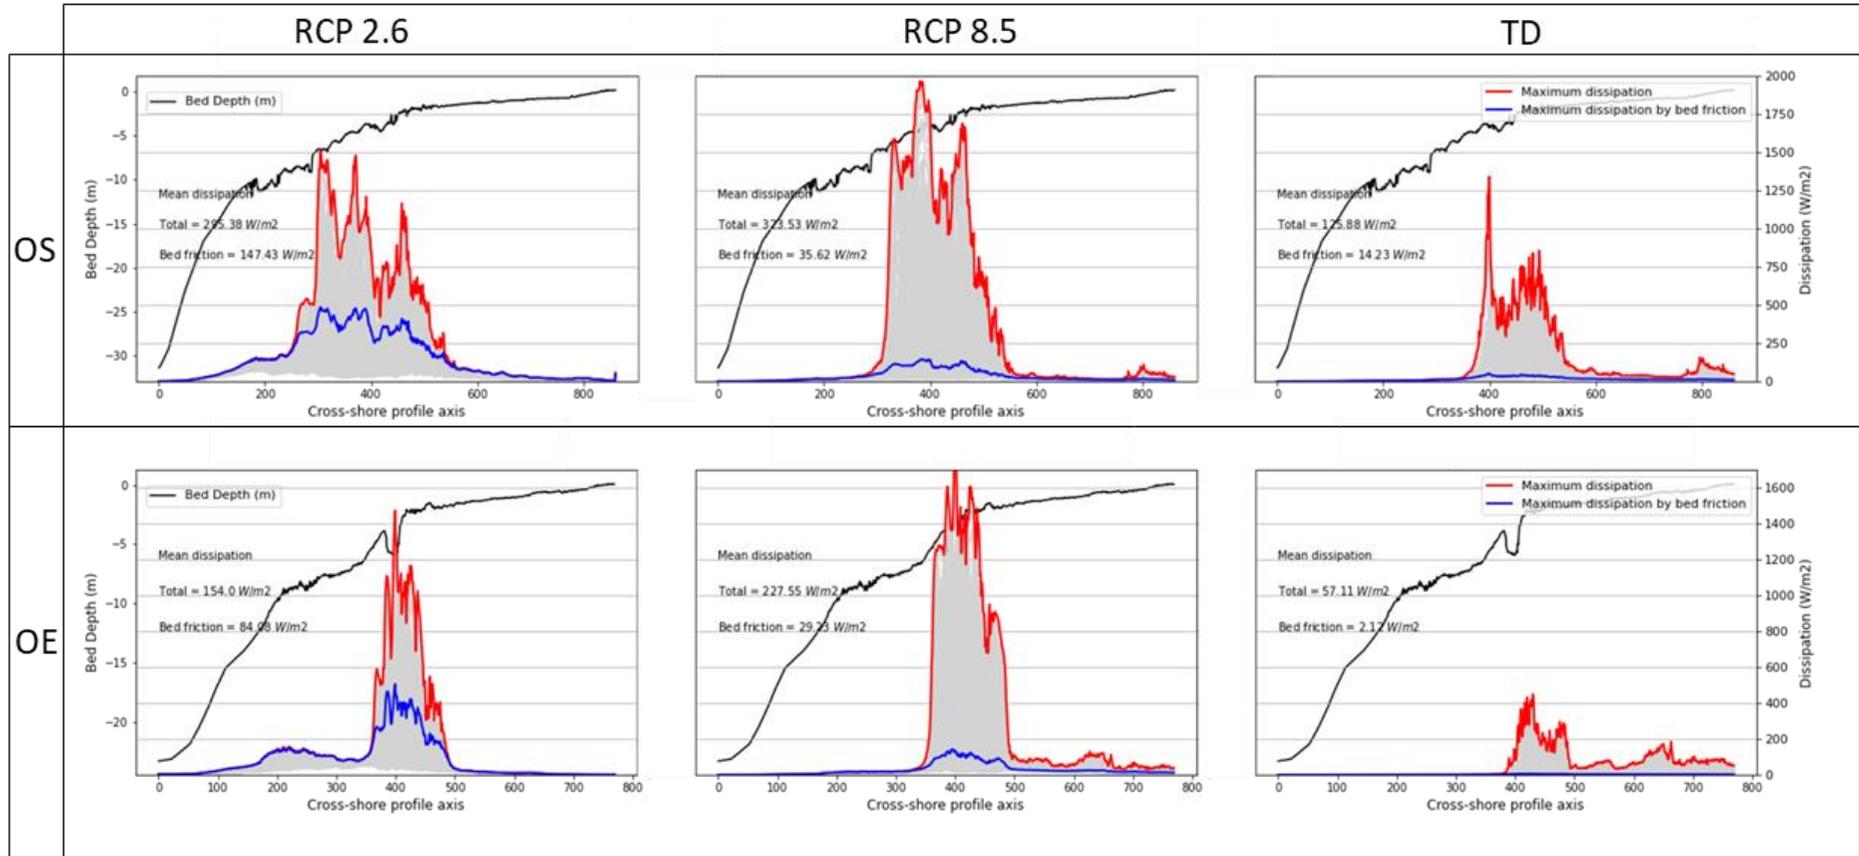

253 3.3 Wave transformation under future climate change projections

254 Wave transformation was found to vary greatly among models depending on climate change
255 scenario, SaG morphometrics, and wave exposure. The largest influence on wave energy dissipation
256 across the two sites was the reduction of the bed friction factor (f_w), increased water depth, and
257 increased wave height. Total wave energy dissipation and dissipation due to bed friction changed at
258 both sites for all future climate scenarios (Table 3).

259 Mean and peak dissipation rates were computed for each site across all three climate scenarios
260 (Table 3, Figure 5). When comparing dissipation rates from present day to RCP2.6 for the year 2100,
261 mean dissipation increased by 187% at site OS (4.4 to 12.5 W/m²) and maximum dissipation
262 increased by 59.7% (946.3 to 1511.4 W/m²) (Figure 5a and b). At site OE, mean dissipation rate
263 increased by 208.6% (2.5 to 7.8 W/m²) and maximum dissipation increased by 217.7% (463.9 to
264 1473.4 W/m²) (Figure 5d and e).

265 When comparing RCP2.6 to RCP8.5 we found a decrease in mean dissipation across site OS of 18.1%
266 (12.5 to 10.6 W/m²) and an increase in the max dissipation rate of 23.2% (1511.4 to 1966.9 W/m²).
267 Site OE retained at high mean dissipation rate from RCP2.6 to RCP8.5, increasing a further 11.7%
268 (7.78 to 8.81 W/m²) and an increase of 19.3% to peak dissipation rate (1473.42 to 1824.70 W/m²).

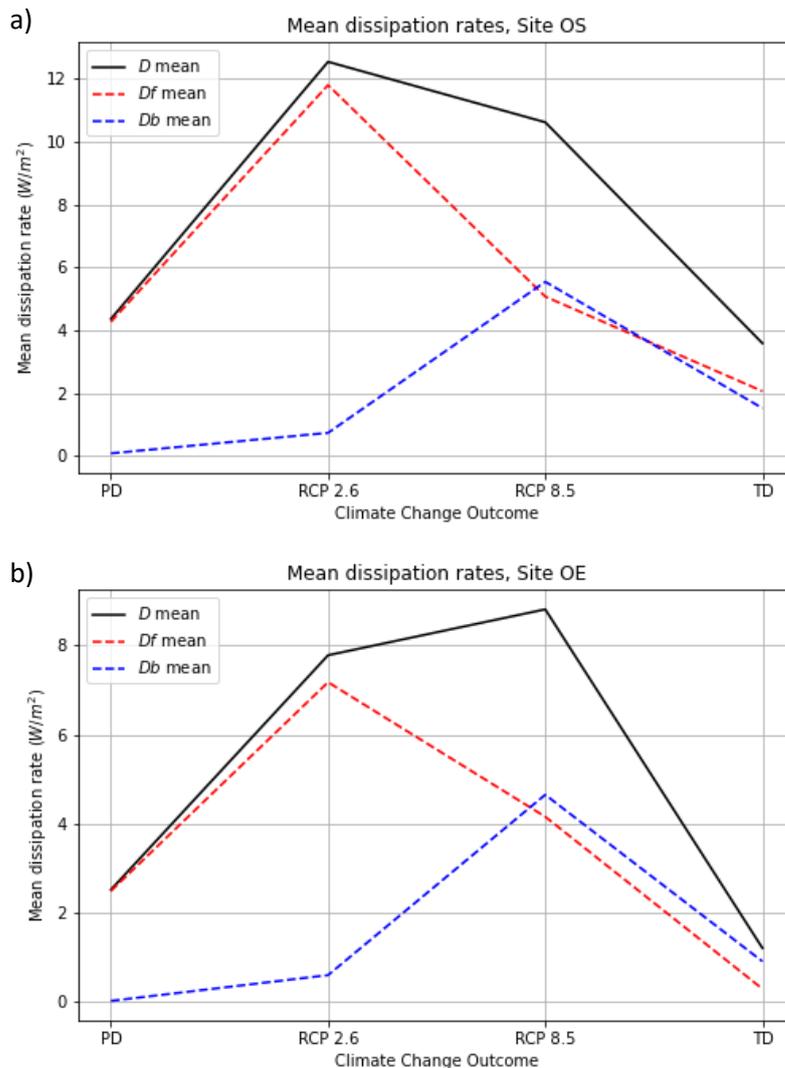

269 When comparing to RCP8.5, the TD scenario, mean dissipation rates decreased by 66.2% (10.61 to
270 3.58 W/m²) at site OS and a decrease in peak dissipation of 31.8% (1966.89 to 1340.93 W/m²)
271 (Figure 4b and c). At site OE, mean dissipation decreased by 86.2% (8.81 to 1.21 W/m²) and peak
272 dissipation rate decreased by 75.4% (1824.7 to 448.24 W/m²) (Figure 5e and f).

273

274 Figure 5: Maximum wave energy dissipation (blue) and dissipation due to bed friction (red) for across the x and time domains, for Site OS under a) RCP 2.6, b)
 275 RCP 8.5 and c) TD climate change outcomes. for site OE under d) RCP 2.6, e) RCP 8.5 and f) TD climate change outcomes. Mean wave energy dissipations are
 276 provided numerically for each plot. Note Y axis are unique for each study site to highlight relative differences in dissipation under variable climate change
 277 outcomes.

278 Under present-day conditions, bed friction is dominant, contributing 98% and 99% of total wave
 279 energy dissipation (Figures 5 and 6). Comparing RCP 2.6 to RCP 8.5, the OS site decreased frictional
 280 dissipation by 57% and at site OE this was 42% (Figure 5 and Figure 6). In this case, dissipation by
 281 wave breaking increased by an average of 659% for both sites. This results in a shift in the dominant
 282 form of wave energy dissipation (Figure 6). Comparing RCP2.6 to the TD scenario, mean frictional
 283 dissipation (D_f) decreases by 82.5% at site OS and 95.8% at site OE while wave breaking remains
 284 marginally greater by 0.1% (OS) and 1.5% (OE) in the TD scenario. Despite this, mean total wave
 285 energy dissipation (the sum of frictional and wave breaking dissipation rates) decreases by 71.4%
 286 (OS) and 84.4% (OE).

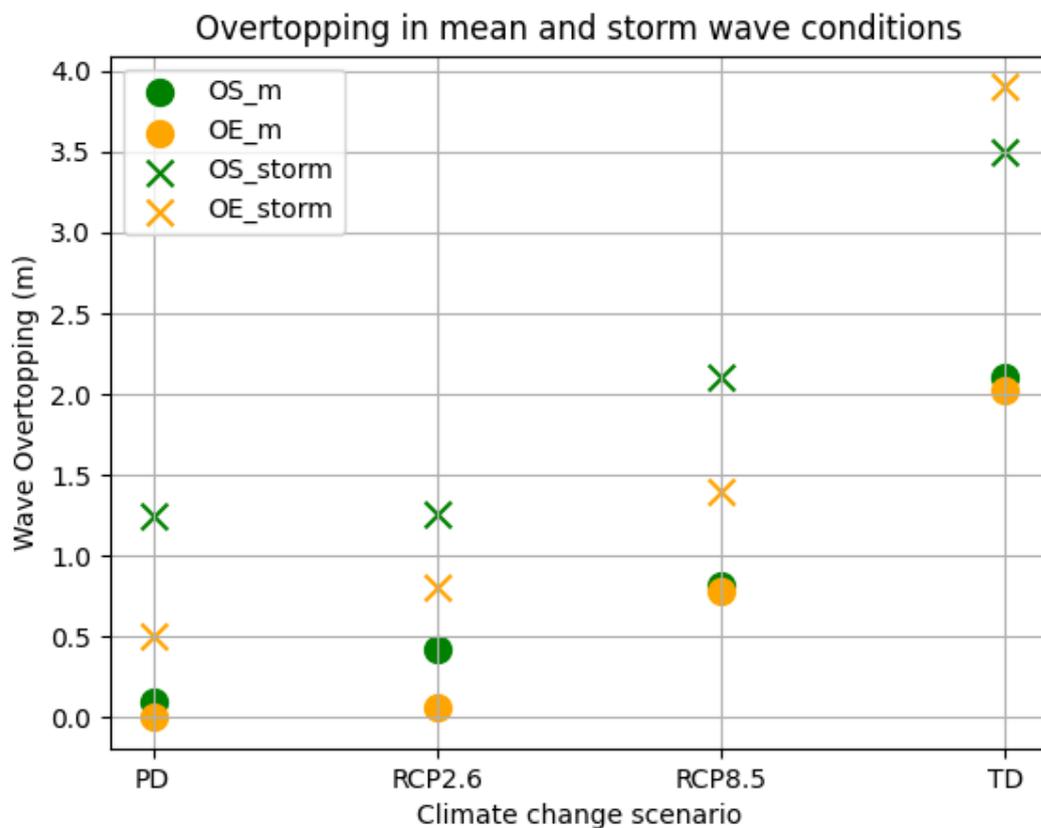

287

288 *Figure 6: Mean total dissipation (D_{mean}) for OS (a) and OE (b) study sites and mean dissipation by*
289 *bed friction (D_f_{mean}) and wave breaking (D_b_{mean}) for each climate change scenario (see Table 3).*

290 We calculated wave overtopping for both sites under present day conditions and three climate
291 change scenarios considering both mean and storm wave conditions (Table 2). For mean wave
292 conditions, wave overtopping in the present-day model was near zero (0 and 0.1 m at site OS and
293 OE, respectively). Wave overtopping increase for all forecast climate change scenarios (Figure 6). We
294 calculated overtopping of 0.4 m at site OS and 0.1 m at site OE for RCP 2.6 with larger increases to
295 0.4 m (OS) and 0.7 m (OE) for RCP8.5. The high emissions scenario (TD) had the highest overtopping
296 of 2.1 m (OS) and 2.0 m (OE).

297 Storm wave conditions increased overtopping compared to mean wave heights in all cases (Figure 7;
298 Table 2). Under present-day conditions, wave overtopping was greater than for mean wave
299 conditions at 1.25 and 0.5 m for site OS and site OE respectively. Under forecast climate change
300 scenarios, storm waves did not significantly impact overtopping under RCP2.6 compared to present
301 day conditions despite an increase in wave height of 3.5 m. Overtopping under RCP8.5 was 2.1 m at
302 site OS and 1.4 m at site OE which increased significantly to 3.5 m and 3.9 m in pessimistic TD
303 models at each site respectively.

304

305 *Figure 7: Wave overtopping at both sites under mean (OS_m and OE_m) and storm (OS_storm and*
 306 *OE_storm).*

307 4. Discussion

308 4.1 Benefits of high-resolution LiDAR-derived bathymetries in numerical wave models

309 Our models of wave transformation over LiDAR-derived bathymetries focus on the influence of SaG

310 morphology on wave energy dissipation and overtopping. Under mean wave conditions we

311 calculated average dissipation rates across the entire forereef profile of 3.61 W/m² at site OS and

312 2.52 W/m² at site OE for offshore wave heights of 1.3 m and 1.2 m respectively. This calculation is

313 made across the entire reef profile representing 862 m and 770 m respectively (Figure 2b, c). Field

314 measurements of wave energy dissipation conducted at OTR were taken at the same site as OE

315 presented in this study (Figure 2c) (Duce et al. 2022). We determined a mean dissipation rate of 10.6

316 W/m² across 60 m between the two instruments, almost entirely due to bed friction (Figure 4 d).

317 Duce et al. (2022) recorded mean dissipation rates of 20 W/m^2 with wave heights of $H_s = 0.78 \text{ m}$ and
318 $T_p = 5$ seconds. Differences in the recorded and modelled data at this site may be attributed to the
319 incident wave direction (N-NE during the deployment period) which was not completely aligned with
320 SaG as modelled here. These results compare with data obtained on a fringing reef in Ipan (Guam)
321 which also featured SaG on the forereef (Péquignet et al., 2011). Between two sensors placed 55 m
322 apart inside a 5 m deep groove, the dissipation rate was 25 W/m^2 for offshore wave heights of 1-2 m
323 (Péquignet et al., 2011). Monismith et al. (2015) identified comparable dissipation rates of 25 W/m^2
324 on a forereef in Palmyra (Kiribati) between instruments 50 m apart for incident wave heights of 1 m.
325 Monismith et al. (2013) determined rates of 22 W/m^2 across a forereef at Mo'orea (French
326 Polynesia) with instruments located 50 m apart and wave heights of 0.3 to 0.5 m. Dissipation rates
327 for each of these studies are assumed to be due to bed friction with constant dissipation between
328 the instruments. Our results indicate that the dissipation rate across the forereef is heterogenous
329 and controlled by the bed morphology (e.g. Figure 5 a). The use of real bathymetries in modelling
330 efforts can elucidate the heterogeneity of dissipation rates on forereefs.

331 Using a real bathymetry, our study demonstrates the influence of groove sinuosity on wave energy
332 dissipation by breaking. Our results show that shore-normal waves interact with spur walls that do
333 not perfectly align with incoming swells. Indeed in our study, the mean groove heading was used to
334 align the bathymetric grids to the oncoming waves (Figure 2b), consistent with field observations
335 (Duce et al., 2020; Munk and Sargent, 1948). Despite this, variation in headings between grooves
336 and the sinuosity of individual grooves produces steep irregularities in the forereef slope that have a
337 large impact on the oncoming waves, playing a significant role on both dissipation by wave breaking
338 and bed friction. The straight and shore normal SaG identified in this analysis (mean sinuosity of
339 $S=0.99$, where 1 is a perfectly straight groove) (Table 4) are representative of groove sinuosity across
340 the southern Great Barrier Reef. For example, observations of 12,102 grooves in the GBR and South
341 Pacific show a mean groove sinuosity of $S = 0.98$ (Duce, 2017). Despite remarkable regional
342 consistency in groove morphology, we observed that even small deviations from perfect shore-

343 normal grooves are significant to wave transformation on the forereef. A more sensitive measure for
344 groove sinuosity may allow for a better understanding of forereef hydrodynamics. Further
345 investigation into SaG sinuosity effects should consider the natural sinuosity of SaG derived from
346 high resolution digital elevation models to account for these effects.

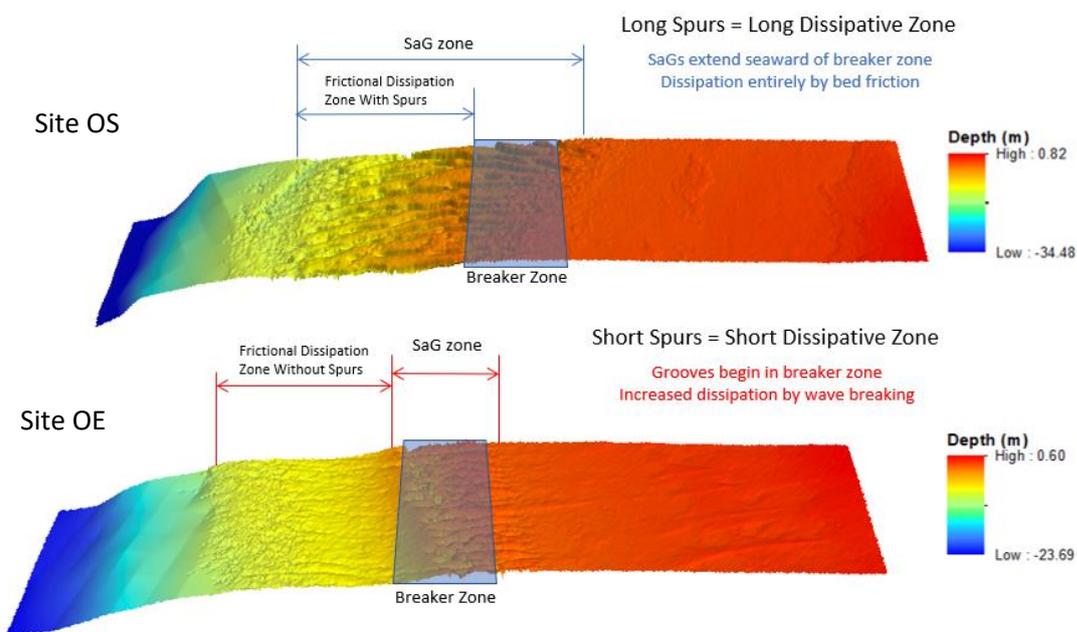

347 **4.2 Effects of SaG from different morphological classes on wave energy dissipation**

348 The most wave exposed site (southern site, OS) has the highest average dissipation rates of 71.5%
349 over 300 m SaG zone due to bed friction (Figure 4a). The long (mean length of 187.12 m) and deep
350 (mean depth of 1.95 m) exposed to wave energy (EWE) grooves at this exposed site may explain how
351 this high average dissipation rate occurred (Table 1). The length of EWE SaG creates surfaces of high
352 frictional drag that extend the zone of frictional dissipation and contribute to high average
353 dissipation rates (Figures 4a and 5). Shore normal currents occurring in the long and deep grooves
354 have also been observed and facilitate high rates of dissipation (Rogers et al., 2013). We
355 demonstrate under present-day conditions that bed frictional dissipation is dominant in dissipating
356 wave energy before breaking occurs at the reef crest (Figure 4a and c). Bed frictional dissipation
357 represents 98.0% and 98.9% of total dissipation at site OS and OE respectively (Figure 4a and c). This
358 is consistent with field research conducted at OTR (Duce et al., 2022) and in other high-energy
359 settings (Lowe et al., 2005; Monismith et al., 2015; Rogers et al., 2017). For example, under mean
360 wave conditions at Palmyra (Kiribati), a high bed friction coefficient ($f_w=1.8$) facilitated greater wave
361 energy dissipation due to bed friction than from wave breaking (Monismith et al., 2015), which is
362 consistent with field observations in Kaneohe Bay, Oahu, Hawaii (Lowe et al., 2005). Our results
363 suggest that the modes of wave energy dissipation (frictional or breaking) are not only influenced by
364 the wave conditions but also by the heterogenous morphology of the forereef slopes.

365 SaG morphology and consequently the morphological classes of Duce et al., (2016) can provide
366 further explanations to the mode of wave energy dissipation (Table 1). Where grooves are shorter,
367 they play a critical role in creating steep bathymetric gradients that induce wave breaking (Figures 4
368 and 8). This differs from previous SaG research (Acevedo-Ramirez et al., 2021) that showed wave

369 breaking being induced by the reef crest. Semi-exposed SaGs (represented here by site OE) are
 370 typically shorter (mean length of 71.5 m) and shallower (mean depth of 1.38 m) than the most
 371 exposed sites (site OS) and can include both exposed to wave energy (EWE) and deep and
 372 disconnected (DaD) classes (Table 1). The seaward extent of the EWE grooves at semi-exposed
 373 forereef sites (OE; Figure 4d) feature a steep bathymetric incline that produces the maximum wave
 374 energy dissipation by wave breaking rate observed across all present-day models (1824.7 W/m^2 ,
 375 Figure 5). As such, long spurs can facilitate frictional dissipation and short grooves can induce wave
 376 breaking by introducing steep bathymetric inclines within the breaker zone of incident waves.

Influence Of EWE Groove Length On Dissipation Area And Mode

377

378 *Figure 8: A comparison between exposed and semi-exposed bathymetric profiles (site OS and site OE)*
 379 *demonstrate the influence of the length of the SaG zone.*

380 The peak in wave energy dissipation at the shoreward of exposed to wave energy (EWE) grooves
 381 highlights the complex interaction between forereef morphological evolution and wave energy
 382 (Figure 4e). The seaward extent of EWE grooves is at a depth of 3.5 m, coincident with the mean
 383 model wave height breaker depth for waves of 1.3 – 4.3 m (Figure 4, Table 2). As wave breaking

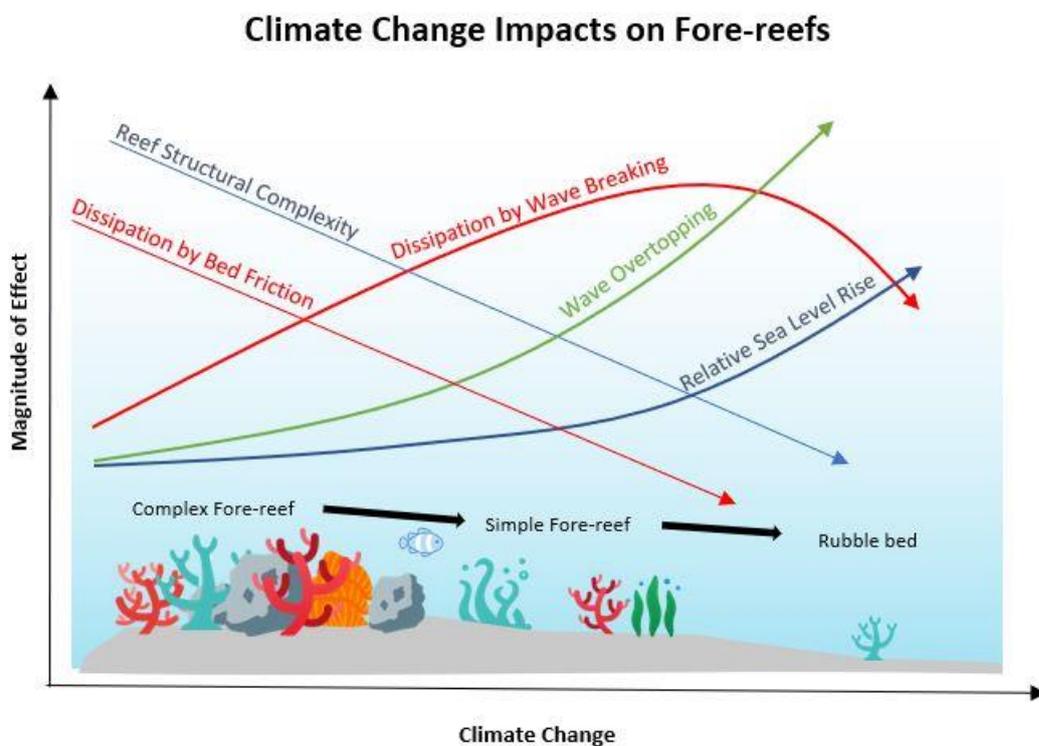

384 imposes forces on the structure of the reef (Massel & Gourlay, 2000; Storlazzi et al., 2005) the
385 results presented here suggest that incident waves could be capable of modifying the EWE grooves
386 in this zone, which is consistent with C14 and U-Th ages of SaG formations on the eastern forereef of
387 OTR (Duce et al., 2020), suggesting an erosive origin for this grooves. Imposed climate change effects
388 further elucidate the influence of grooves. Deep and disconnected (DaD) grooves at site OE exist
389 below the typical wave base and have minimal interaction with present day wave energy. Supporting
390 the previous findings that DaD grooves may be relict features, formed at an early stage during the
391 Holocene transgression (Duce et al., 2016).

392 4.3 The impact of climate change on wave energy dissipation over SaG

393 Forecasted environmental changes decrease mean wave energy dissipation (Figure 5) which is
394 consistent with other approaches (e.g., Quataert et al., 2015; Sheppard et al., 2005). In the
395 simulations presented here, dissipation remains high between RCP 2.6 and RCP 8.5 as reduced
396 dissipation by bed friction is balanced by an increase in dissipation by wave breaking (Figures 5 and
397 6). The difference between dissipation by bed friction and dissipation by wave breaking is the
398 greatest at both sites for RCP 8.5, where water depth is still sufficient for wave breaking, yet the
399 degradation of the reef reduces frictional effects (see Figure 9). A reliance on wave breaking
400 dissipation is consistent with observations from high energy reefs of low structural complexity
401 (Harris et al., 2018). Finally, dissipation is lowest where SLR is greatest (TD scenario) due to wave
402 passing over the reef without breaking (Figure 9). Although the role of SLR is thought to be
403 secondary in contributing to these changes (Harris et al., 2018), our models suggest that the
404 combined impact of SLR and loss of structural complexity will lead to lowest dissipation rates
405 (Figures 5 and 9) and highest wave overtopping (Figures 6 and 9) under future climate change
406 scenarios.

407 Sea-level rise (SLR) shifts the region of high energy dissipation toward the reef-crest (Figure 5b, c and
408 e, f). Bathymetric features that are submerged into the surf zone by rising relative sea level are likely

409 to influence wave breaking and frictional dissipation (Figure 5). This is evident in the shoreward
 410 shifting dissipation zones (Figure 5) and as previous literature states (Massel and Gourlay, 2000) is a
 411 threat to corals in this zone as wave breaking results in greater hydrodynamic forces on corals.
 412 Corals previously protected from wave energy are likely to be species of lower mechanical strength
 413 (Storlazzi et al., 2005). Under worse case scenarios (RCP 8.5) by the year 2100 it is likely that corals
 414 of the same species may be weaker due to lower carbonate saturation in the water column (Eakin,
 415 1996) or high frequency bleaching events (Hughes et al., 2017). Coral breakage is likely to occur here
 416 and the corals that support a steep bathymetric incline with a high frictional coefficient responsible
 417 for this peak in wave energy dissipation may have lower structural resilience by 2100 (Eakin, 1996).
 418 High-energy SaG formations have been attributed to wave induced erosion, albeit at vastly different
 419 timescales to sedimentary swash-zone features such as rip channels (Duce et al., 2020). It is possible
 420 that climate change-driven increase in erosive forces promote further SaG development on
 421 forereefs, which contributes to the dissipation of wave energy.

422

423 *Figure 9: A conceptual diagram of changes to wave transformation on forereefs under increasing*
424 *climate change impacts. Climate driven inputs including loss of reef structural complexity and relative*
425 *sea-level rise are shown (blue). Dissipation rates (red) due to bed friction decreases, in response,*
426 *dissipation due to wave breaking increases until water depth exceeds breaker depths. Wave*
427 *overtopping (green) increases exponentially due to the combined effects of relative sea-level rise and*
428 *loss of reef structural complexity.*

429 4.3.2 Potential for wave overtopping with climate change

430 Wave overtopping exponentially increases with climate change due to the coupled effects of
431 decreased bed friction and loss of dissipation due to breaking (Figure 7). Compared to mean wave
432 conditions, the impact of storm waves results in increasingly greater overtopping when climate
433 projections are increased. (Figure 7). This effect is persistent despite the increased wave energy
434 dissipation at the semi-exposed forereef (site OE) under RCP 8.5 (Figure 4e). The primary control on
435 wave overtopping is sea-level rise, which incorporates eustatic and local sources. Future work should
436 include tidal effects, which would contribute an additional 1.5 m of water level at mean spring high
437 tide at OTR (Harris et al., 2015). The magnitude of wave overtopping observed in the TD scenario at
438 the exposed site (OS) of ~4 m is sufficient to entirely flood all backreef environments at OTR,
439 including the low-lying coral island. This magnitude of wave overtopping would have significant
440 impacts on coral reef islands and reef-lined shores (Fellowes et al. 2022; Storlazzi et al. 2015;
441 Talavera et al. 2021). For example, 3.7 m of wave run up combined with sea surface elevation above
442 a reef flat in Roi-Namur, Marshall Islands, was observed in flooding of inland area of the Island
443 (Cheriton et al., 2016). Research elsewhere demonstrated that wave overtopping on reef islands in
444 the year 2100 will be highly variable across due to variable reef vertical accretion and erosion rates
445 (Beetham and Kench, 2018; Kench et al., 2022), but also due to the vertical accretion of coral reef
446 islands (Kench et al., 2019, 2022; Masselink et al., 2020) which is controlled by sediment availability.

447 The combined influence of coral reef degradation and sea-level rise amplifies the occurrence of
448 wave overtopping, thereby exposing communities located in the downwind direction of coral reefs
449 to heightened risks of flooding (Harris et al., 2018; Quataert et al., 2015; Storlazzi et al., 2018).
450 Notably, a maximum overtopping of approximately 4 m was measured here when the significant
451 wave height reached 5.1 m. An examination of altimeter data reveals that within the 33-year data
452 span, wave heights have not surpassed this threshold (95th percentile wave height = 3.1 m) (Figure
453 S1, supplementary material). Consequently, further investigation is required to determine the
454 frequency of significant overtopping events at OTR.

455 5. Conclusion

456 This study combined numerical modelling and LiDAR-derived bathymetry to demonstrate the
457 importance of forereef spur and groove (SaGs) morphologies in modifying wave energy. Results
458 indicate that high resolution digital elevation models (< 1 m) can provide morphometric data to
459 examine wave transformation on forereefs comparable to field studies. We show that groove
460 sinuosity plays a role in wave transformation and should be considered in future research on wave
461 dissipation on forereefs. This highlights the need for accurate bathymetries in future studies of
462 forereef wave energy dissipation, as idealized bathymetries used in previous studies, using
463 numerical or physical modelling, cannot provide results comparable to field studies.

464 We demonstrate that SaG morphological classes exhibit distinct dissipation characteristics, with
465 some showcasing higher frictional dissipation and others exhibiting greater breaking dissipation.
466 Notably, spur length emerges as a critical factor in enhancing dissipation by bed friction. Among the
467 SaG morphological classes, exposed to wave energy (EWE) grooves have demonstrated the most
468 substantial dissipation rates, while deep and disconnected (DaD) grooves contribute less to the
469 dissipation process, particularly evident under future climate change scenarios.

470 Projected climate change conditions may lead to a decrease in wave energy dissipation on forereefs.
471 Indeed, the climate change scenarios analysed demonstrated that changes in the mode of wave
472 energy dissipation will likely occur. The most notable result was a decrease in dissipation by bed
473 friction from 100% of dissipation under present day conditions to 48% under RCP 8.5. This is
474 matched by a 52% increase in dissipation by wave breaking. Overall, we found a loss in wave energy
475 dissipation under future climate change scenarios leading to increased wave overtopping, with the
476 maximum overtopping occurring where dissipation was lowest. Forereef morphological adjustment
477 to increased dissipation by wave breaking may expose corals to erosion, a process which has been
478 linked to the formation of SaG. The results highlight the critical role of forereef morphology in wave
479 energy dissipation and the need for measures to promote coral growth to facilitate future
480 dissipation. The findings have implications for the modelling wave transformation over forereefs to
481 provide insight into the future habitability of exposed reef-lined coasts.

482 6. Acknowledgements

483 We acknowledge the Gadigal people of the Eora Nation, the traditional owners of the land and
484 waters where this research was conducted, and pay respects to their elders past, present and
485 emerging. We acknowledge the cultural significance of the Southern Great Barrier Reef, where we
486 conduct fieldwork, to the Tarebilang Bunda, Bailai, Gooreng Gooreng and Gurang Traditional
487 Owners. Lachlan Perris was supported by an RTP scholarship from The University of Sydney and the
