

22 Plain language summary

23 In 2020, an intense unrest period took place on the Reykjanes peninsula,
24 in southwest Iceland, preceding the Fagradalsfjall volcano eruption in 2021.
25 The unrest was characterized by ground movements of several centimeters
26 (measured by GNSS stations) and accompanied by an increased number of
27 local earthquakes. We investigate whether the unrest affects velocities of
28 seismic waves that propagate through the crust in Reykjanes. Instead of
29 conventional seismometers, we use seismic data recorded by a fiber optic
30 cable. This technology has the advantage that measurements can be made
31 every few meters along the cable. We exploit this high spatial sampling
32 to improve methods traditionally applied to seismometer records. These
33 improvements enable us to infer seismic velocity changes as a function of
34 time and space along the fiber optic cable. We detect velocity changes that
35 strongly correlate with the observed ground deformation in Reykjanes and
36 are, therefore, likely linked to the unrest and/or its associated processes.

37 1. Introduction

38 Coda wave interferometry is a frequently used technique to detect struc-
39 tural and dynamic changes in the Earth’s crust (e.g., [Snieder et al., 2002](#);
40 [Grêt et al., 2006](#)). This method is used to measure seismic wave velocities
41 as a function of time. At first, measurements were applied to the coda of
42 earthquake records, which constitute the long tail of phases following the
43 earthquake signals (e.g., [Chouet, 1979](#); [Baisch and Bokelmann, 2001](#)). Be-
44 cause coda waves experience multiple scattering, they have longer propaga-
45 tion paths in the Earth than direct waves. Thus, they are more sensitive to

46 changes in the subsurface (e.g., [Snieder et al., 2002](#); [Obermann et al., 2016](#);
 47 [Martins et al., 2020](#); [Toledo et al., 2022](#)). However, monitoring requires that
 48 the sources are repeatable (e.g., [Snieder and Hagerty, 2004](#); [Hadziioannou](#)
 49 [et al., 2009](#)). While active sources are perfectly repeatable but costly, earth-
 50 quakes occur at irregular (mostly unpredictable) discrete points in time.

51 Information about Earth can also be extracted from ambient seismic
 52 noise, which is, for example, generated by ocean microseisms: Interactions
 53 between atmosphere, ocean gravity waves and the solid Earth continuously
 54 induce seismic energy (e.g., [Longuet-Higgins, 1950](#); [Hasselmann, 1963](#)). Due
 55 to the continuity of the recordings, measurements of velocity variations at
 56 any time can be made. This has been exploited in a diverse range of re-
 57 search, including the monitoring of glaciers and landslides (e.g., [Mainsant](#)
 58 [et al., 2012](#); [Larose et al., 2015](#); [Voisin et al., 2016](#); [Guillemot et al., 2020](#);
 59 [Bontemps et al., 2020](#)), fault zones (e.g., [Wegler and Sens-Schönfelder, 2007](#);
 60 [Breguier et al., 2008](#); [Liu et al., 2018](#)), volcano-related processes (e.g., [Mor-](#)
 61 [dret et al., 2010](#); [Sens-Schönfelder et al., 2014](#); [Donaldson et al., 2017](#); [Hirose](#)
 62 [et al., 2017](#)), hydraulic systems (e.g., [Hillers et al., 2014](#); [Illien et al., 2022](#))
 63 and geothermal systems (e.g., [Obermann et al., 2015](#); [Sánchez-Pastor et al.,](#)
 64 [2019](#); [Toledo et al., 2022](#)). One drawback of these studies is that datasets
 65 consist of discrete points in space where seismic stations are deployed and
 66 therefore lack spatial density, such that detected velocity variations can only
 67 be attributed to large geographic areas between stations. This limits the
 68 ability to resolve small-scale responses of crustal rocks. Another limitation is
 69 that, in order to increase the signal-to-noise ratio (SNR) of data and obtain
 70 reliable measurements, data are usually stacked over time (e.g., [Larose et al.,](#)

71 [2008]. This makes the measurements less sensitive to short-term environ-
72 mental processes.

73 Distributed dynamic strain sensing (also called DAS) is a technique that
74 transforms an optical fiber into a dense array of strain sensors (e.g., [Zhan,
75 2019; Lindsey and Martin, 2021]). In multiple studies, it has been shown that
76 DAS resolves structure and dynamics of the sub-surface at unprecedented
77 spatial resolution and at low cost compared to conventional seismometers
78 (e.g., [Jousset et al., 2018; Lindsey et al., 2019; Zhan, 2019; Williams et al.,
79 2019; Jousset et al., 2022; Diaz-Meza et al., 2023]). In the context of ambient
80 noise, DAS has been applied to obtain dispersion curves (e.g., [Dou et al.,
81 2017; Luo et al., 2020; Shao et al., 2022; Song et al., 2022; Zhou et al., 2022])
82 and extract body waves through cross-correlation ([Tonegawa et al., 2022]).
83 Velocity changes caused by ground water fluctuations were tracked along a
84 DAS cable near the Sacramento river in the US ([Rodríguez Tribaldos and
85 Ajo-Franklin, 2021]).

86 Our study focuses on the Reykjanes peninsula (SW Iceland), where an
87 intense unrest period took place in 2020 in the area of the Svartsengi geother-
88 mal field (Figure 1). The unrest period consisted of three episodes of crustal
89 inflation between January and August of 2020 and preceded a series of erup-
90 tions ([Flovenz et al., 2022]). Each inflation episode was followed by crustal
91 deflation and associated with a large number of small to moderate earth-
92 quakes ($M < 4.8$). Using ocean microseisms recorded by DAS, we measure
93 seismic velocity changes in the crust beneath Reykjanes. Data come from
94 the GFZ database ([Jousset et al., 2020]) and comprise 5.5 months between
95 March and August of 2020, thereby covering two of the three inflation peri-

ods. The two questions driving our research are:

1. How can we exploit the spatial resolution of DAS to improve coda wave interferometry?
2. Do measurements of seismic velocity variations correlate with the deformation between March and August of 2020 or associated processes?

We address these questions by first applying the conventional workflow of coda wave interferometry (e.g., Brenguier et al., 2008; Steinmann et al., 2020) using single DAS channels in order to obtain measurements of velocity changes over time (Section 2). Then, we systematically investigate how the spatial resolution of DAS can be exploited to improve the temporal and spatial resolution of velocity changes (Sections 4 and 5). Finally, we interpret our results geologically (Section 6).

2. Data and Processing (conventional workflow)

The 21-km long fiber-optic cable is located on top of the mid-ocean ridge on the Reykjanes peninsula in the south-west of Iceland (Figure 1). The fiber was originally part of the telecommunication network in Reykjanes until it was repurposed as a strain sensor in seismological measurements (Jousset et al., 2018). Strain rate ($\delta\epsilon/\delta t$) records cover 164 days between March 1st and August 14th, 2020 (no data was provided on the 31th of each month) at a sampling rate of 1000 Hz, a channel spacing of 4 m and a gauge length of 10 m. During the measurements in 2020, the iDAS interrogator (Parker et al., 2014) was located in the town of Grindavik.

118 Because of computational constraints, we analyze a subset of the data,
 119 focusing on two 1.2 km-long sections of the fiber, each comprising approxi-
 120 mately 300 channels (Figure 1). These sections, designated as SectionE (east)
 121 and SectionW (west) based on their geographical orientation, were selected
 122 because they are roughly co-linear on the DAS cable. This configuration is
 123 suitable for extracting stable Rayleigh waves through seismic interferometry,
 124 given that the Fresnel zones are sufficiently covered by ambient noise sources
 125 (e.g., Martin et al., 2021). Our objective is to measure velocity variations in
 126 the subsurface between SectionE and SectionW over time.

127 2.1. Pre-processing and cross-correlation

128 We process strain rate data with 24 hour long data segments. For com-
 129 putational efficiency, we decimate our data to a sampling rate of 5 Hz, which
 130 is in agreement with the frequency range of interest for our analysis. We
 131 subtract the mean and remove linear trends from the time series. We filter
 132 the data with a second-order zero-phase butterworth-bandpass filter retain-
 133 ing frequencies between 0.5 Hz and 0.9 Hz. This filter was chosen because
 134 frequencies higher than 0.9 Hz resulted in poor data quality and typical fre-
 135 quencies of the secondary microseisms (0.1 Hz - 0.4 Hz) could not be exploited
 136 due to the dominant impact of nearby isolated noise sources.

137 The core of the processing is cross-correlation of passive data recorded at
 138 different channels to extract empirical Green's functions between the chan-
 139 nels, thereby turning one channel into a virtual source and the other channel
 140 into a receiver. This is also commonly referred to as ambient noise inter-
 141 ferometry (e.g., Wapenaar et al., 2010). Prior to cross-correlation, we apply
 142 one-bit normalization (e.g., Bensen et al., 2007) by setting the amplitudes to

143 either -1 or 1 depending on their sign, in order to minimize spurious arrivals in
 144 empirical Green's functions due to more than 20,000 local earthquakes (Fig-
 145 ure 9). We also apply spectral whitening using a running average ("rma")
 146 over 100 points within our cut-off frequencies 0.5 Hz and 0.9 Hz in order to
 147 reduce the influence of monochromatic signals in the cross-correlations (e.g.,
 148 Bensen et al., 2007; Cupillard et al., 2011; Prieto et al., 2011). To start, we
 149 only include 28 channels from each section with an equidistant spacing of
 150 40 m in the analysis (in total 56 channels). The reasoning behind this is to
 151 initially obtain results using the selected single traces. Later in this study,
 152 we will exploit the full spatial resolution of DAS and isolate the effect on the
 153 results when all 300 channels from each section are included in the analysis.

154 Throughout this work, channels on SectionE will be indexed with num-
 155 bers 0-27, channels on SectionW with numbers 28-55 (Figure 2). We compute
 156 daily "intra-section" cross-correlations, thus cross-correlations between chan-
 157 nels on SectionE and SectionW (e.g., cross-correlation of data recorded by
 158 channel 0 on SectionE and channel 34 on SectionW). Using this approach, we
 159 retrieve empirical Green's functions sampling the medium between the two
 160 sections.

161 2.2. Coda wave interferometry

162 To measure velocity variations over time, the stretching method is used
 163 (e.g., Lobkis and Weaver, 2003; Hadziioannou et al., 2011). This technique
 164 determines an optimal stretching factor ϵ that accounts for the degree of
 165 stretching or compression of a waveform relative to a reference waveform.
 166 The perturbation of the waveform is assumed to be linear $\tau = \epsilon t$, where τ
 167 is the arrival time of the wave in the altered and t in the reference medium

168 and ϵ quantifies the stretching or compression. Measurements are done on
 169 the coda waves that follow the direct surface waves in the retrieved Green's
 170 functions, because coda waves are particularly sensitive to changes in the
 171 medium. We define reference waveforms for each channel combination as
 172 the mean of daily cross-correlations over the entire time period (164 days).
 173 Perturbed (stretched or compressed) waveforms are defined as the mean over
 174 a shorter time interval in which a change of the medium properties is assumed
 175 to have happened. The determination of this time interval is presented in
 176 detail in Section 4 and leads to a value of 21 days. Thus, the measurement
 177 of velocity variation for a given channel combination and day d results from
 178 comparing the mean of 21 ($d - 10$ to $d + 10$) daily cross-correlations to the
 179 reference trace.

180 To quantify the stretching for a given perturbed waveform, a grid search is
 181 carried out. Perturbed waveforms are artificially stretched with a reasonable
 182 range of stretching parameters ϵ . For each ϵ , Pearson correlation coefficients
 183 (e.g., Hartung, 2009) are computed between the artificially stretched wave-
 184 form and the reference trace for the coda wave time window. The stretching
 185 parameter that yields the highest correlation coefficient is linked to the rel-
 186 ative velocity variation $\epsilon = -\frac{dV}{V}$. We define the coda window as the time
 187 period between 9 to 26 seconds following the direct surface waves arrival.
 188 The arrival time of the direct wave is estimated by dividing the distance
 189 between the virtual source and receiver by the velocity of the direct waves
 190 (determined through beamforming (Figure S1)). We perform the grid search
 191 in two steps: at first, we use a coarse grid and test 100 evenly spaced values
 192 between $\epsilon = -0.05$ and $\epsilon = 0.05$, corresponding to velocity changes between

193 -5% and 5%. This yields a first estimate of the optimal stretching parameter
 194 ϵ_{est} , or velocity change dVV_{est} , respectively. In a second step, the grid search
 195 is repeated but for a finer grid, including 100 evenly spaced values between
 196 $\epsilon_{est} - 0.002$ and $\epsilon_{est} + 0.002$ ($dVV_{est} - 0.2\%$ and $dVV_{est} + 0.2\%$). For each
 197 combination of channels and day, this procedure is carried out separately on
 198 the acausal and causal part of the cross-correlations. To reduce instabilities
 199 in the results caused by, for example, an inhomogeneous source distribution,
 200 we stabilize measurements by averaging over the causal and acausal parts.

Figure 1: Top: The DAS cable is located at the south-western edge of the Reykjanes peninsula (red square in the small map of Iceland). The selected fiber sections (SectionE and SectionW), the approximate location of the Svartsengi geothermal area, GPS station SKSH and the point of maximum uplift are indicated. White and bright yellow lines represent roads. The centre of the deformation observed between March and August of 2020 coincides with the geothermal area. Bottom: Vertical ground displacement measured by GPS station SKSH. Outliers were removed prior to display. Two cycles of inflation and deflation (shaded in grey) were observed during our time period.

Figure 2: Selected fiber sections. Channels on SectionE are labelled with numbers 0-27, channels on SectionW with numbers 28-55. Positions of channels 32, 42, and 52 for which results will be shown are schematically indicated.

201 3. Exploiting the spatial resolution of DAS

202 Using beamforming techniques (Rost and Thomas, 2002), we estimate the
 203 apparent subsurface velocity of direct surface waves in our frequency range
 204 (0.5 - 0.9 Hz) to be 1.93 km/s (Figure S1). Thus, we expect apparent wave-
 205 lengths between 2.14 km and 3.86 km in our data. Because these wavelengths
 206 are much larger than the channel spacing of 4 m, we assume that adjacent
 207 channels on the fiber record effectively the same waveform. This suggests
 208 that we can stack adjacent traces in space without introducing bias to the
 209 recorded wavefield, in order to increase the SNR of the data. In the context
 210 of ambient noise interferometry, spatial stacking of large-N arrays and DAS
 211 has been successfully applied to improve the stability of retrieved Green's
 212 functions, e.g., in order to reveal body waves in cross-correlations (e.g., Lin
 213 et al., 2013; Wang et al., 2014; Nakata et al., 2015; Tonegawa et al., 2022)
 214 and improve surface wave dispersion measurements (e.g., Shragge et al., 2021;

215 [Czarny and Zhu, 2022](#); [Li et al., 2022](#); [Jousset et al., 2022](#); [Cheng et al., 2023](#)).
216 It is important to emphasize that we measure velocity changes in the coda of
217 cross-correlations. In contrast to direct waves, the coda resembles a diffuse
218 wavefield constituting waves coming from all directions. This means that
219 the conventional delay-and-sum approach (as used in beamforming) in which
220 the SNR of a seismic phase can be boosted by time-shifting and stacking
221 traces based on a specific slowness value and backazimuth, is not suitable
222 for improving the SNR of coda waves. However, apparent wavelengths (2.14
223 km to 3.86 km) exceed the inter-station distance of 4 m by many orders of
224 magnitude, which should allow us to simply stack traces in space without
225 applying any time shifts. An unknown at this point is how many traces we
226 can stack spatially without causing destructive interference of waveforms and
227 corrupting the original coda wavefield. To answer this question, we carry out
228 a synthetic study that is presented in the following section.

229 *3.1. Synthetic parameter study*

230 To investigate the question up to which spatial distance waveforms can
231 be stacked, we use a synthetic approach rather than real data. This has the
232 advantage that the results are not affected by poor data quality due to low
233 SNRs or by strong amplitude variations caused by, for example, differences
234 in the coupling of the fiber. We first create a harmonic wave propagating in
235 the positive x -direction. The displacement u of the wave at position x_i with
236 $i \in [0, 1, \dots, 125]$ and time t is given by

$$\begin{aligned}
u(x_i, t) &= \cos(kx_i - \omega t) + N(\sigma, x_i, t) \\
&= \cos\left(\frac{2\pi}{\lambda}x_i - 2\pi ft\right) + N(\sigma, x_i, t)
\end{aligned} \tag{1}$$

237 where λ is the wavelength, k the wave number, f represents the frequency
 238 and N denotes Gaussian random noise with standard deviation σ registering
 239 between 0.5 Hz and 0.9 Hz, since this is the frequency range of interest. We
 240 mimic our DAS cable and compute displacements for x -positions separated
 241 by 4 m, thus $[x_0 = 0, x_1 = 4, x_2 = 8, x_3 = 12, \dots, x_{125} = 500]$ m.. We
 242 further simulate our real data setting by inserting $\lambda = 2.14$ km (previously
 243 determined with beamforming) and $f = 0.9$ Hz. For each position x_i we
 244 define a stack S as the mean of all traces trace between x_0 and x_i

$$S(x_i, t) = \frac{1}{i+1} \sum_{j=0}^i u(x_j, t). \tag{2}$$

245 This is equal to averaging over a spatial distance $x_i - x_0$. Figure 3 illus-
 246 trates this procedure. In order to quantify the alteration of the waveform
 247 due to spatial stacking, we compute Pearson correlation coefficients between
 248 the stacks and the initial waveform $u(x_0, t)$ at all positions x_i , i.e. for in-
 249 creasing spatial stack lengths $L \in [0, 4, 8, \dots, 500]$ m. We also investigate the
 250 dependency on the noise level, which is defined by the standard deviation
 251 $\sigma \in [0, 0.2, 0.4, \dots, 10]$ of the Gaussian noise distribution. Results are shown
 252 in Figure 4. The longer the stack length and the higher the noise level, the
 253 smaller the correlation coefficients. Thus, the optimal spatial stack length
 254 for a given wavelength and frequency is controlled by the degree of random

255 noise in the data. We define a threshold at a stack length of $L = 200$ m,
 256 which corresponds to 50 adjacent traces on the DAS cable. Depending on
 257 the level of random noise, correlation coefficients between <0.80 and 0.95
 258 are expected for this stack length. Assuming low noise levels, these correla-
 259 tion coefficients seem high enough to guarantee that no bias is caused to the
 260 original wavefield.

Figure 3: a-c) Time series $u(x_i, t)$ at positions $[x_0 = 0, x_1 = 4, x_2 = 8, x_3 = 12, \dots, x_{50} = 200]$ m due to a harmonic wave travelling in the positive x-direction. Three different noise levels in a) $\sigma = 0$ (no noise), b) $\sigma = 4$ and c) $\sigma = 9$ are considered. d-f) Stack $S(x_{50}, t)$ (mean of all times series u between $x_0 = 0$ m and $x_{50} = 200$ m) is plotted together with the waveform $u(x_0, t)$ for three different noise levels in d) $\sigma = 0$ (no noise), e) $\sigma = 4$ and f) $\sigma = 9$. For example, the stack shown in e) is the mean of all traces shown in b).

261 3.2. New workflow based on spatial stacking of DAS data

262 Using the results from the synthetic study that was presented in the pre-
 263 vious section, we carry out spatial stacking with the decimated data before

Figure 4: Correlation coefficients CC between the stacked waveforms $S(x_i, t)$ and the initial waveform $u(x_0, t)$ at $x_0 = 0$ m. The optimal spatial stack length L for a given frequency and wavelength depends on the degree of random noise contained in the data. At a stack length of $L = 200$ m (red dashed line), correlation coefficients of approximately 0.95 are expected for low noise levels.

any further pre-processing or cross-correlation is applied. In order to system-
 atically investigate the effect that spatial stacking has on the results, we test
 different values $L \in [24, 48, 96, 144, 200]$ m. Thus, we generate 5 additional
 sub-datasets based on different spatial stack lengths. Table 1 summarizes
 the properties of each sub-dataset. Stacks are computed via

$$u_L(x_k, t) = \frac{1}{N+1} \sum_{l=k-\frac{N}{2}}^{l=k+\frac{N}{2}} u(x_l, t) \quad (3)$$

where $u(x_k, t)$ is the recorded strain rate at time t and position x_k with
 $k \in [1, 2, \dots, 300]$ (300 channels on each section). Hence, each stack is the mean
 of $N+1$ traces, separated by 4 m, with central position x_k . We evaluate this

272 formula for all previously selected channels $j \in [0, 1, \dots, 55]$ on SectionE and
 273 SectionW (see Section 2). For each sub-dataset, we perform the processing
 274 steps described in Section 2.

Sub-dataset	L [m]	N	Percentage of smallest wave- length
Single traces	0	0	0
1	24	6	1.1
2	48	12	2.2
3	96	24	4.5
4	144	36	6.7
5	200	50	9.3

Table 1: Properties of each sub-dataset. In addition to the single traces for which no spatial stacking was applied, we generate 5 datasets based on different spatial stack lengths L (or the number of stacked DAS channels $N + 1$, respectively). The maximum spatial stack length $L = 200$ m corresponds to 9.3% of the smallest dominant wavelength (2.14 km) in our data.

275 4. Improving temporal resolution

276 The stretching method was introduced earlier in this work and quanti-
 277 fies the degree of stretching or compression of a perturbed waveform relative
 278 to a reference waveform. Perturbed waveforms are thereby defined as the
 279 mean of traces over a certain time interval $T_s + 1$. A very low T_s (short time
 280 interval) implies a high time resolution but also low signal-to-noise ratios
 281 (SNRs) which can introduce bias to the measurements and lead to unreliable
 282 results. A very large T_s (long time interval) lowers the time resolution of

283 measurements, smearing out short-term environmental processes of interest.
 284 To define T_s , we examine two parameters: For an increasing temporal stack
 285 length, we evaluate i) the Pearson correlation coefficient and ii) the SNR be-
 286 tween stacked cross-correlations and reference traces. The SNR is defined as
 287 the fraction of the maximum amplitude of the coda window (picked between
 288 9 and 26 seconds after the direct surface wave arrival) and the standard de-
 289 viation of the noise window (a 16 seconds long time window at the tail of
 290 cross-correlations). Figure 5 shows the result for a selected channel combi-
 291 nation. The larger the number of stacked daily cross-correlations, the higher
 292 the correlation coefficients and SNRs. The optimal temporal stack length T_s
 293 is chosen where correlation coefficients converge towards a value of 1 (reach
 294 a stable plateau), given that SNRs show a robust evolution in time (e.g.,
 295 Larose et al., 2008; Steinmann et al., 2020). Following this, we set $T_s = 20$
 296 days. It is apparent that this value depends on the spatial stack length L .
 297 For instance, with single traces and a short spatial stack length of $L = 24$ m,
 298 correlation coefficients have not yet stabilized at the chosen value of $T_s = 20$
 299 days, indicating that a higher T_s might be more appropriate to obtain reli-
 300 able results. Conversely, with $L = 200$ m, an even shorter T_s would suffice.
 301 This is a valuable result: stacking raw data in space before cross-correlation
 302 enhances time resolution in coda wave interferometry. The larger the spatial
 303 stack length, the higher SNRs and the faster the convergence of correlation
 304 coefficients. However, in all following analyses, we maintain $T_s = 20$ days
 305 across all spatial stack lengths to isolate the impact spatial stacking has on
 306 the results.

Figure 5: SNR and waveform coherency (correlation coefficients CC between the reference waveform and temporally stacked cross-correlations) for an increasing stack length in days (channel combination 3_42). Results for both the causal and acausal side of the cross-correlations are shown. The larger the spatial stack length L , the higher the SNRs and the faster the convergence of correlation coefficients. The dashed grey lines at $T_s = 20$ mark the temporal stack length chosen for our analysis.

307 5. Results - velocity changes

308 5.1. Visualization

309 Our goal is to spatially and temporally resolve processes related to the de-
 310 formation. The area affected by the ground deformation as observed in GNSS
 311 data matches the area of the geothermal field, and thus covers DAS channels
 312 on SectionE (Figure 1). We therefore present our results as follows: We select
 313 a reference channel on SectionW and plot results for all combinations of sta-
 314 tions on SectionE and the selected channel in 2-dimensional "gathers" (e.g.,
 315 Figure 6). Using this approach, we track spatio-temporal changes in seis-
 316 mic velocities along SectionE relative to a fixed reference point on SectionW.

317 Throughout this work, we will present results from three reference channels
 318 (32, 42, 52), situated respectively at the eastern end, in the middle, and at
 319 the western end of SectionW, to illustrate the range of outcomes across the
 320 entire section (Figure 2).

321 5.2. Effect of the spatial stack length

322 Figure 6 shows results for reference channel 42 on SectionW. In the case
 323 of the single traces, velocity variations look rather randomly distributed, al-
 324 though spatial coherency in some places can be suspected, for example in
 325 July. Correlation coefficients vary; at the beginning of May, June and July,
 326 particularly low values are measured. For a stack length of $L = 24$ m (1.1
 327 % of the smallest dominant wavelength), the spatial and temporal coherency
 328 is considerably improved. Overall, larger correlation coefficients are mea-
 329 sured. Areas of decreased and increased wave speeds can be more clearly
 330 distinguished and trends start to emerge in the results. Outliers, i.e., par-
 331 ticularly strong deviations represented by oversaturated colors, are reduced
 332 in number. The spatial and temporal coherency of velocity changes further
 333 improves with each increase in L , accompanied by growing correlation coeffi-
 334 cients. Trends in the data stabilize, allowing a clear spatio-temporal pattern
 335 of velocity changes to be observed: an area of increased wave speed is re-
 336 vealed and the end of March and April that is first detected by channels in
 337 the north-east of SectionE and, as time passes, by channels in the south-
 338 west. The same trend can be observed at the beginning of June and July. In
 339 between those time periods, lower than average velocities are measured. Fi-
 340 nally, for $L = 200$ m (9.3 % of the smallest dominant wavelength) the highest
 341 spatio-temporal coherence and largest correlation coefficients are obtained.

Figure 6: Gathers for an increasing spatial stack length L (reference channel 42). Correlation coefficients (CC) with values < 0.7 and their corresponding velocity changes (dVV) are not displayed. Results for the easternmost station are shown at the bottom, results for the westernmost station on SectionE are displayed at the top of each gather. Thus, by going from the bottom to the top along the y-axis, we move from the north-east to the south-west along SectionE (see also Figure 2). Inflation periods are marked with horizontal arrows below the time axis. With each increase of L , CCs are higher and the spatial and temporal coherency of velocity variations is improved.

Results for reference channels 32 and 52 (Figures S2 and S3) underscore the improving spatio-temporal coherency in the results as the spatial stack length increases.

5.3. Spatio-temporal variability and evolution

Results differ slightly depending on which reference channel is chosen on SectionW (Figure 7a-c)). For example, stations 19-27 on SectionE in combination with reference channel 42 measure increased velocities in March, but lower velocities in combination with reference channel 52 (dotted squares in Figure 7b and c). These differences may be due to local effects beneath the channels on SectionW, such as the coupling of the fiber and local geology. Thus, differences in the results reveal valuable information about the subsurface near the reference channels. The main trends, that is, time periods and areas of decreased and increased wave speeds are, however, similar for all reference channels. To quantify the main trends and in order to isolate processes that happen beneath SectionE, we smooth out local effects at SectionW and compute an average by stacking all (twenty-eight) gathers. The result is shown in Figure 7d). Overall, velocities drop at the beginning of the first inflation period. This is followed by a velocity increase (feature 1 in Figure 7d) until they reach a local maximum at the beginning of the first deflation period with higher than average values. From there, seismic wave speeds decrease until they reach a local minimum at the beginning of the second inflation period. This is again followed by a velocity increase as the second inflation period goes on (feature 2). Striking is that velocity changes tend to be first measured by channels in the north-east, and then, as time passes, by channels in the south-west of SectionE. For example, higher than

average wave speeds are measured by channels in the north-east at the end of the first and during the second inflation period (features **A** and **B** in Figure 7d)). The time at which these increased velocities are picked up by the westernmost channel coincides with periods of crustal deflation. This channel is very close to the point at which the maximum uplift in the area was observed (Figure 1).

6. Discussion

6.1. Smoothing effect due to spatial stacking

In order to improve SNRs of data in the context of coda wave interferometry, temporal stacking is usually applied which comes at the expense of time resolution. With spatial stacking, DAS provides another option to improve SNRs which compensates for temporal stacking (Figure 5). Similar to temporal stacking, there is a smoothing effect as we average over a spatial distance and may thus blur out localized velocity variations on individual channels. In return, however, we achieve a time resolution that allows us to capture short-term deformation cycles over a relatively short total time period of 5.5 months (Figures 6 and 7). In general, the extent to which spatial stacking is beneficial depends on the specific objectives of the study. Nevertheless, we note that while spatial stacking may smooth out local velocity changes, typical seismological datasets inherently lack sufficient spatial resolution at the meter-scale to capture such nuances. We further introduce a smoothing effect by selecting every 10th channel along the fiber sections with a 40-meter separation as virtual source/receiver, and gradually extending the spatial stack length from 24 m to 200 m. This is because for spatial

Figure 7: a-c) Gathers for reference stations 32, 42, 52 (see Figure 2 for the station locations). The easternmost station on SectionE is displayed at the bottom, the westernmost station on SectionE is shown at the top of the gathers as described in Figure 6 and indicated with the arrows. Results for a spatial stack length $L = 200$ m are shown. Above each gather, the spatial averages (mean over all station pairs) are plotted with standard deviations. Inflation periods are shaded with grey color. The black dotted squares in b) and c) indicate an area for which different results were obtained for reference channels 42 and 52 (see text). d) Average over all (twenty-eight) gathers. Velocity changes tend to be first picked up by channels in north-east and later in the south-west of SectionE.

391 stack lengths $L \geq 48$ m, virtual sources overlap (multiple virtual sources are
 392 included in the stacks). Such smoothing effects are inherent in distributed
 393 dynamic strain sensing (DAS) due to the gauge length typically exceeding the
 394 channel spacing. Our method can be seen as a systematic expansion of the
 395 gauge length up to a predetermined threshold (defined through the synthetic

parameter study) that ensures preservation of the original coda wavefield.

6.2. Bias introduced by spatial stacking and synthetic parameter study

It is important to discuss whether spatial stacking could introduce bias by causing an apparent stretching of the waveforms. This scenario may occur, for instance, if the distribution of the noise source is not uniform, as we illustrate through the following line of thought: if the position of the noise source changes over time, the radiation pattern at the virtual source, changes. Through cross-correlation, a different part of the Earth's crust may be emphasized, potentially resulting in different incident angles of the wavefront arriving at the receivers. This may cause that a different fraction of the (apparent) wavelength is stacked on one day compared to another day and introduce an apparent stretching. However, how variations of the noise source distribution affect the coda of cross-correlations, is generally a matter of debate (e.g., [Froment et al., 2010](#); [Colombi et al., 2014](#)). Recent research indicates that coda waveforms may be dominated by isolated noise sources continuously activated at specific locations, rather than by fully scattered waves ([Schippkus et al., 2023](#)). This means that isolated noise sources may contribute to velocity changes identified with the stretching method, questioning the common assumption that measurements of velocity changes on coda waves originate in structural and dynamic changes in the subsurface only. Further analyses will help to identify potential pitfalls of spatial stacking in the context of coda wave interferometry, similar to the synthetic study presented in this paper. This parameter study is founded on several assumptions: the assumption of Gaussian random noise, considered independent across the channels, is a simplification. In reality this unwanted noise

421 might be coherent across multiple channels and get enhanced through spa-
 422 tial stacking. Similarly, we assume that no local or isolated ambient noise
 423 sources are present that introduce spurious arrivals prone to amplification.
 424 Hence, analogous assumptions to those commonly employed in ambient noise
 425 interferometry are made, wherein the synthetic parameter study mirrors the
 426 ideal scenario of a homogeneous and non-variable noise source distribution.
 427 Nevertheless, it serves as an initial framework upon which further numerical
 428 simulations and synthetic examples can build.

429 *6.3. Discrepancy between causal and acausal side*

430 We averaged over causal (positive) and acausal (negative) sides of cross-
 431 correlations. This is usually done in order to account for instabilities due
 432 to, for example, an inhomogeneous noise source distribution. Provided that
 433 the wavefield is fully scattered, we expect similar measurements on both
 434 sides of the correlations. However, different, but spatially coherent results
 435 are obtained for the causal and acausal parts, as demonstrated in Figure 8.
 436 Measurements on the acausal sides are smaller in magnitude and tend to
 437 show the opposite trend compared to the causal side. Weemstra et al. (2016)
 438 apply coda wave interferometry in our study region using ambient seismic
 439 noise. They use a very similar processing scheme and measure contradicting
 440 stretching values on the causal and acausal sides for similar frequencies (0.5
 441 - 1 Hz). The authors argue that this may be associated with a variable
 442 distribution of noise sources. Reykjanes is located at the south-western edge
 443 of Iceland such that the noise sources in the Atlantic ocean likely are in close
 444 proximity to the stations. A change in the noise sources thus has a greater
 445 impact on the measurements. Our observations suggest that the noise source

446 distribution affects our measurements and that the wavefield is not entirely
447 diffuse. This implies that measurements may not be solely attributable to
448 structural changes in the crust. Still, we observe a compelling correlation
449 between geological processes and our measurements, which we discuss in the
450 following.

Figure 8: Comparison between acausal and causal side. Means over all (twenty-eight) gathers are displayed for a spatial stack length of $L = 200$ m. Spatially averaged velocity changes with standard deviations are displayed for causal and acausal sides at the top. Inflation periods are shaded with grey color. Contradicting, but spatially coherent velocity changes are measured on both sides of the cross-correlations.

451 6.4. Correlation with deformation and associated processes

452 We compare the averaged results to ground deformation and associated
453 seismicity (Figure 9 and Figure S4). GPS data are from station SKSH which
454 is located in the geothermal area close to SectionE (Figure 1). Constant
455 trends and values deviating more than two times the standard deviation from
456 the mean were removed prior to display. Because of the divergence of the
457 North-American and Eurasian plate, we remove linear trends from the hori-
458 zontal components. During vertical crustal inflation, the ground in SectionE
459 exhibits slight westward movement, whereas it moves towards the east dur-
460 ing subsidence. Negligible displacement is measured on the N-component.
461 Except for the beginning of the analysed time period, spatially averaged
462 velocity changes are positively correlated with the Z-component and the W-
463 component of the GPS instrument. We exclude the possibility that changes
464 in seismic velocities are caused by the static displacement. Measured veloc-
465 ity changes are of the order of 0.05%. Ground displacements observed at the
466 GPS station are of the order of 5 mm horizontally and 8 cm vertically, which
467 would result in length changes of the seismic raypath and thus, expected ve-
468 locity changes of 0.00007% and 0.001%, calculated for the minimum distance
469 of 7 km between virtual source and receiver. These values are three and one
470 order of magnitude smaller than our measurements.

471 A link between vertical ground deformation in volcanic regions and changes
472 of seismic velocities has been proposed in previous research. Numerous stud-
473 ies find a negative correlation between vertical ground motion and veloc-
474 ity changes (decreasing velocities during inflation). This has mostly been
475 linked to magmatic intrusions, magma pressurization and associated open-

476 ing of cracks and fractures (e.g., [Brennguier et al., 2008](#); [Duputel et al., 2009](#);
 477 [Mordret et al., 2010](#); [Sens-Schönfelder et al., 2014](#); [Bennington et al., 2015](#);
 478 [Cubuk-Sabuncu et al., 2021](#)). Positive correlations (increasing velocities dur-
 479 ing inflation) were also found, for example prior to an eruption at Merapi vol-
 480 cano ([Ratdomopurbo and Poupinet, 1995](#)) and at Kilauea volcano ([Donald-
 481 son et al., 2017](#)), and related to compression of the edifice caused by magma
 482 pressurization and closure of cracks. Thus, the same geological mechanisms
 483 have been invoked for interpretation of opposing measurements of velocity
 484 variations, and the subsurface geology, e.g., the existence of fissures and faults
 485 as well as the porosity and compressibility of rocks greatly affects the nature
 486 of the correlation. [Donaldson et al. \(2017\)](#) emphasize the importance of the
 487 depth of the inflating source and the resulting distribution of compressional
 488 and extensional strain in the crust. If seismic waves are sensitive to an area
 489 that undergoes extensional strain, a negative correlation between vertical
 490 ground deformation and velocity changes would be expected, and vice versa.
 491 [Cubuk-Sabuncu et al. \(2021\)](#) also infer velocity changes in Reykjanes
 492 during the unrest period by applying coda wave interferometry to broad-
 493 band seismic stations. They detect net decreased velocities between January
 494 and August of 2020 across different frequency ranges and relate this to re-
 495 peated magmatic intrusions at ≈ 4 km depth and the concurrent opening of
 496 cracks. However, the authors analyze a much longer time period (up to ≈ 3
 497 years) which also covers 'quiet' times without deformation, while our entire
 498 analysis time period (5.5 months) falls into the unrest period of 2020. Thus,
 499 a comparison of the studies is challenging as our dataset doesn't provide the
 500 temporal resolution necessary to compare seismic velocities during the unrest

501 period to seismic velocities during quieter times. Interestingly, the authors
502 find that stations in the north-east of the inflating region measure a decrease
503 in velocity prior to stations in the west of the inflating zone. The tendency
504 for velocity changes to be measured first in the east and then in the west is
505 generally consistent with our observations.

506 Flovenz et al. (2022) propose a model for the observed deformation in
507 Reykjanes, in which each inflation period is caused by the intrusion of mag-
508 matic fluids into an aquifer at approximately 4 km depth. The aquifer re-
509 sembles the approximate shape and location of the geothermal field outlined
510 in Figure 1. The fluids are assumed to originate from a deeper sub-crustal
511 source of melt east of the geothermal area and migrate along the brittle-
512 ductile-boundary into the aquifer from the east to the west. Crustal inflation
513 starts as the fluids reach the aquifer and create an overpressure large enough
514 to lift the crust above it. We investigate whether our results could be asso-
515 ciated with the fluid infiltration into the aquifer. Previous research indicates
516 that seismic waves in our used frequency range (0.5 Hz to 0.9 Hz) and study
517 area are particularly sensitive to structure in the upper few kilometers of
518 the crust (Weemstra et al., 2016; Cubuk-Sabuncu et al., 2021) and may thus
519 be affected by the fluid infiltration. Hence, the positive correlation between
520 vertical ground motion and velocity changes could be associated with com-
521 pression of the edifice caused by intruding fluids and closure of cracks. As
522 fluids recede during crustal deflation, the crust relaxes, causing a decrease of
523 wave velocities.

524 Velocity changes are also correlated with the W-component of the GPS-
525 instrument (Figure 9a)). Generally, velocities increase as the ground moves to

526 the west, and decrease, as the ground moves to the east. For the first inflation
 527 period, there is a slight mismatch in time between dVV measurements and
 528 GPS data: while the ground starts to move towards the west at the beginning,
 529 the onset of the velocity increase is in the middle of the first inflation period.
 530 Discrepancies in timing between velocity changes and ground displacement
 531 could arise from the fact that we average velocity variations over both Sec-
 532 tionE and SectionW. Consequently, our measurements encompass different
 533 geological conditions, such as fluid saturation and stress distribution in the
 534 crust, captured by all channels across the 1.2 km-long fiber segments. This
 535 may lead to differences compared to the GPS instrument, which only provides
 536 a single-point measurement of ground displacement, and to imperfect corre-
 537 lations between ground displacement and velocity changes. However, we note
 538 that the discrepancy is much less pronounced on measurements obtained for
 539 the causal sides of cross-correlations (Figure S5), indicating a possible con-
 540 nection with the contradictory measurements on causal and acausal sides as
 541 discussed in the previous section.

542 The link between velocity changes and horizontal ground deformation
 543 may again be associated with the infiltration of fluids from the northwest
 544 to the southeast at a depth of ≈ 4 km, inducing pressurization and stress
 545 transfer within the subsurface during inflation, followed by crustal relaxation
 546 during deflation as the fluids retreat. However, the fact that DAS measures
 547 along the axial direction of the fiber (e.g., [Martin et al., 2021](#)), which in
 548 our case implies that it is particularly sensitive to variations in strain in the
 549 NE-SW direction, could contribute to our observations. We conclude that
 550 we can not yet provide a solid explanation for the correlation between our

551 measurements and the W-component of the GPS instrument. If and how the
552 directivity of DAS affects the measurements would have to be investigated
553 in future research.

554 We also explore a potential link between our findings and the spatio-
555 temporal distribution of seismicity with a particular focus on our observa-
556 tion that velocity changes are first picked up by channels in the north-east
557 and later in the south-west. During the analysed time period, more than
558 20,000 local earthquakes occurred in our study area. Seismic activity inten-
559 sifies during crustal inflation and diminishes during deflation (Figure 9c) and
560 d)). Depths range between several meters and 10 km, with most events being
561 shallower than 5 km. Events are particularly shallow beneath the geothermal
562 field where the brittle-ductile boundary domes up and deeper further away
563 from it (Flovenz et al., 2022). We find no evidence of an initial occurrence
564 of earthquakes further in the east followed by a subsequent westward pro-
565 gression over time, however, we cannot rule out that seismicity affects our
566 measurements.

567 Overall, our results suggest a strong link between unrest periods in Reyk-
568 janes from March to mid-August of 2020 and seismic velocity changes. Ground
569 deformation, fluid intrusions and local seismicity influence the stress distribu-
570 tion in the upper few kilometres of the crust during our time period. However,
571 associating measured velocity changes with a specific geological mechanism
572 is challenging, because all these processes happen at the same time and in-
573 fluence the measurements in possibly opposite ways. Also, the fact that
574 different measurements are obtained for causal and acausal sides of cross-
575 correlations (Section 6.3) suggests that the noise-source distribution affects

576 our measurements, and that the results may not be solely be attributable to
577 structural changes in the crust. This raises the question to what extent our
578 measurements can be interpreted geologically.

579 Even though not fully understood, our results demonstrate the potential
580 of spatial stacking to improve the spatial coherency of velocity variations and
581 increase their time resolution. With the applied technique, we were able to
582 find a strong correlation between velocity variations and ground deformation
583 at time scales that would not have been achievable with the classical workflow
584 where no spatial stacking is applied. This motivates to further explore the
585 power of DAS - its high spatial sampling - to enhance existing processing
586 techniques and strategies for monitoring.

Figure 9: Geological interpretation of the results. On the x-axes, time is shown. Inflation periods are shaded with grey color. a) and b) Comparison between measurements and GPS data (W-, and Z-component). Standard deviations are not plotted for better visual comparison. c) and d) Cumulative number of earthquakes and spatio-temporal evolution of seismicity. Earthquake data are from two independent catalogues: events from the IMO catalogue are plotted in color with depths and magnitudes, events from the GFZ catalogue (Heimann et al. 2021), which captures a higher number of events but no magnitudes, in the background. The cumulative number is derived from the GFZ catalogue.

587 7. Conclusions and Implications

588 In this study, we combined ambient noise interferometry and DAS to mon-
589 itor velocity variations in Reykjanes, south-west Iceland, between March 1
590 and August 14 of 2020. During this period of time, two inflation episodes of
591 the crust, each followed by deflation, were observed. Using a methodological
592 approach, we systematically explored what DAS adds as new contribution to
593 seismic monitoring studies due to its high spatial resolution. We then inves-
594 tigated the link between geological processes and estimated temporal seismic
595 velocity changes. Finally, we answer the questions posed in the introduction
596 (Section 1).

597 **How can we exploit the spatial resolution of DAS to improve**
598 **coda wave interferometry?**

599 We developed a new workflow based on spatial stacking of the raw data
600 prior to cross-correlation, which affects measurements of relative velocity
601 variations in two ways: (i) Time resolution is gained, which makes the mea-
602 surements more sensitive to short-term environmental processes (Section 4).
603 This confirms that DAS can detect structural and dynamic processes in the
604 Earth that would not be identifiable with conventional datasets with compar-
605 atively sparse spatial sampling. (ii) Spatial stacking significantly improves
606 the spatial and temporal coherency of the measurements, enabling us to re-
607 liably track changes in the sub-surface in time and space (Section 5). These
608 findings have implications for various fields of research, such as the moni-
609 toring of ground water flow, magmatic intrusions and human infrastructure.
610 They may help improve our understanding of stress transfer in the Earth
611 and our ability to assess risks in hazardous areas. Finally, we emphasize that

612 spatial stacking of the raw data efficiently reduces the computational cost in
613 noise-based interferometric studies, as the number of cross-correlations to be
614 computed usually scales with the square of the number of involved traces.
615 By stacking spatially prior to cross-correlation, the information about the
616 wavefield contained in each trace further contributes to the analysis, which
617 is in contrast to discarding traces, which carries the risk of losing valuable
618 information.

619 **Do measurements of seismic velocity variations correlate with**
620 **the deformation between March and August of 2020 or associated**
621 **processes?**

622 Measured velocity changes correlate positively with ground displacement
623 in both W- and Z-direction. This suggests a strong link between our mea-
624 surements and the deformation. Overall, seismic velocities tend to be first
625 picked up by channels in the north-east and at later times by channels in
626 the south-west. Our results may be associated with pressure changes at
627 depth and an associated redistribution of stress in the crust, induced by the
628 northeast-southwestwards directed propagation of fluids at 4 km depth. How-
629 ever, it was found to be difficult to establish a causal relationship between
630 our findings and a specific geological process. Situated atop the spreading
631 mid-ocean ridge, the DAS cable occupies a volcanic zone characterized by
632 a complex tectonic and geologic environment. Within this setting, various
633 phenomena such as seismic activity, the migration of fluids, crustal deforma-
634 tion and the presence of high-temperature geothermal areas all influence the
635 waveforms simultaneously and in different ways. What ultimately defines the
636 nature of the correlation between ground deformation and seismic velocity

637 changes also depends on the geology of the subsurface and its response to
638 the complex interaction of concurrent mechanisms.

639 In addition, different measurements are obtained for the causal and the
640 acausal sides of cross-correlations which suggests that our measurements may
641 not be based on fully scattered wavefields. While measured velocity changes
642 are larger in magnitude for the causal sides and thus mainly make up for
643 the trends observed in the averaged results, measurements on the acausal
644 sides seem to show the opposite trend and thus anti-correlate with ground
645 deformation in the Z- and the W-direction. This suggests that a quantitative
646 geological interpretation might currently be constrained by conceptual
647 limitations that need to be confronted in the future.

648 Overall, our observations not only showcase the capacity of DAS to unveil
649 Earth processes at unprecedented resolution, but also to disclose and better
650 understand limitations associated with current seismological methods. In
651 future research, this knowledge will contribute to the enhancement of existing
652 methods and ultimately help to improve our understanding of the Earth
653 system's dynamic processes.

654 Open Research

655 The GFZ earthquake catalogue presented in this research is freely available
656 ([Heimann et al., 2021](#)). Seismic data are provided by the GFZ Potsdam
657 and are available in the GEOFON repository ([Jousset et al., 2020](#)). GPS
658 data were downloaded from the open database of the IMO ([Icelandic Met
659 Office, 2024](#)). Cross-correlations were computed with a self-modified version
660 of the Python program "NoisePy" ([Jiang and Denolle, 2020](#)).

661 Acknowledgements

Introduction

This supporting information provides Figures S1 to S5 as referenced in the main text.

For data shown in Figure S1, processing is described in Text S1.

Text S1: Beamforming

Beamforming was applied to a separate dataset including every 50th channel along the 21-km long DAS cable and 30 days of data from March 2020. Empirical Green's functions were extracted using ambient noise interferometry. At first, a virtual source was selected. Then, daily cross-correlations between the virtual source and all other channels were computed in the frequency range 0.5 Hz - 0.9 Hz and subsequently stacked to increase the signal-to noise ratio (SNR) of cross-correlations. Results are displayed in the correlation gather in Figure S1a). Beamforming was applied to a subset of the data with good SNR (Figure S1b) and yields an apparent velocity of 1.93 km/s (Figure S1c).

Figure S1. Beamforming. Data processing is described in Text S1. a) Correlation gather showing cross-correlations between the virtual source (red star) and all other stations. The subset used for beamforming is marked with the grey dashed line. The black line indicates the moveout corresponding to the best-fitting wave velocity 1.93 km/s obtained with beamforming. b) Wiggle traces for data subset marked in a) and traces after shifting them using the best-fitting velocity. c) Beamforming result. A grid search was applied to a reasonable range of slownesses in the X (longitude) and Y (latitude).

Figure S2. Gathers for an increasing spatial stack length L (reference channel 32). Figure caption as in Figure 6 in the main text.

Figure S3. Gathers for an increasing spatial stack length L (reference channel 52). Figure caption as in Figure 6 in the main text.

Figure S4. Comparison between ground deformation in Reykjanes (station SKSH, see Figure 1 in main text) and seismic velocity changes (dVV). Standard deviations are not plotted for better visual comparison. The west (W), vertical (Z) and north (N) components are shown.

Figure S5. Comparison between vertical and horizontal (E-W) ground deformation in Reykjanes (station SKSH, see Figure 1 in main text) and seismic velocity changes (dVV), measured for causal and acausal sides of cross-correlations individually. Standard deviations are not plotted for better visual comparison.
