Key Points:

- Cumulatively, Lagrangian coherent eddies have anomalously high surface chlorophyll relative to dispersive eddies and outside-eddy waters.
- The biological response to eddy trapping differs regionally, seasonally, by eddy age, and polarity.
- Coherent Hawaiian Lee eddies have the most extreme chlorophyll anomalies year-round relative to outside-eddy waters.

Abstract

Vertical motions associated with mesoscale ocean eddies modulate the light and nutrient environment, stimulating anomalies in phytoplankton biomass and chlorophyll. Phytoplankton populations can be subsequently trapped by the horizontal circulation or laterally diluted. In a time-varying flow, Lagrangian methods can be used to quantify eddy trapping, also known as Lagrangian coherency. From two decades of remote sensing observations in the North Pacific Subtropical Gyre, we compared coincident Eulerian and Lagrangian eddy atlases to assess the impact of eddy trapping on chlorophyll concentration. We found higher chlorophyll within Lagrangian coherent boundaries than in Eulerian eddies and outside-eddy waters. Yet, there are differences regionally and seasonally. For example, chlorophyll is most enriched within coherent boundaries of the Hawaiian Lee eddies and to the south of 23°N in fall and winter. Our results suggest that by not accounting for lateral dilution, Eulerian analyses may underestimate the role of mesoscale eddies in enhancing chlorophyll.

Plain Language Summary

Eddies are ubiquitous rotating ocean currents up to hundreds of kilometers in diameter. While some eddies continuously mix with their surroundings, others trap their constituents that do not escape until the eddy dissolves. We refer to the former eddy behavior categorically as leaky or dispersive, while the latter is coherency. Phytoplankton are microscopic, free-floating microbes subject to the whims of ocean currents, including eddies. They contain the pigment chlorophyll within their cells that allows them to photosynthesize and subsequently alter the color of the ocean. In this study, we used satellite datasets and simulations of currents in the North Pacific to examine the effect of eddy coherency on local concentrations of phytoplankton, estimated by the greenness of the surface ocean. We found little difference in chlorophyll concentration in leaky and coherent eddies north of the Hawaiian Islands. To the south, we observed significantly greener waters in coherent eddies than in their leaky counterparts in the winter and fall. We suggest that, in some regions, studies may underestimate the role of leaky eddies in stimulating plankton blooms if they are quickly mixed with surrounding waters, which has implications for the ocean carbon budget.

1 Introduction

The North Pacific Subtropical Gyre (NPSG) has low phytoplankton biomass but is subject to high ecosystem variability (Karl & Church, 2017). Mesoscale eddies contribute to this variability, bringing nutrient-rich deep waters to the oligotrophic surface of the gyre via eddy-wind interactions and eddy pumping that stimulates phytoplankton growth (McGillicuddy Jr, 2016). Eddies in the NPSG including Station ALOHA and the Hawaiian Lee eddies are the focus of seminal works capturing biophysical interactions. For example, observations reveal that eddies affect biogeochemical cycling by enhancing primary production (Falkowski et al., 1991; Allen et al., 1996; Nicholson et al., 2008), altering phytoplankton community structure (Olaizola et al., 1993; Vaillancourt et al., 2003; Brown et al., 2008; Fong et al., 2008; Barone et al., 2019; Harke et al., 2021), and intensifying carbon export (Bidigare et al., 2003; Benitez-Nelson et al., 2007; Rii et al., 2008; Zhou et al., 2021). The NPSG is Earth’s largest ecosystem, thus the integrated effects of mesoscale biophysical interactions therein may play a significant role in the global carbon cycle.

Ocean eddies also influence the horizontal advection of phytoplankton, potentially acting to isolate communities (Provenzale, 1999) and preserve them across ocean basins (Lehahn et al., 2011; Villar et al., 2015). Further, lateral trapping can modulate trophic interactions (d’Ovidio et al., 2013) and generate plankton patchiness by localizing blooms (Gower et al., 1980; Fennel, 2001). In this study, we refer to eddies that trap for months

or longer as “coherent”. Mesoscale eddies that are detected from the Sea Level Anomaly (SLA) by assuming geostrophic balance (Chelton, Schlax, & Samelson, 2011; Chelton, Gaube, et al., 2011) are not necessarily coherent through time (Beron-Vera et al., 2013; Wang et al., 2015). To accurately measure eddy coherency in a time-varying flow, a Lagrangian perspective is needed (Haller, 2015). Interpreting biophysical interactions from a Lagrangian perspective naturally follows since phytoplankton experience a moving frame of reference (Woods & Onken, 1982; Lehahn et al., 2018).

Satellite remote sensing of SLA and chlorophyll-*a* (chl-*a*; a proxy for phytoplankton biomass) reveals significant relationships between ocean color anomalies and mesoscale eddies in subtropical waters (Gaube et al., 2014; Dufois et al., 2016; He et al., 2016; Huang et al., 2017; Xu et al., 2019; Travis & Qiu, 2020). However, these studies employ Eulerian methods and cannot determine the contribution of eddy trapping toward altering chl-*a* concentrations. By comparing complementary Lagrangian and Eulerian eddy atlases, we tested the hypothesis that the waters within coherent vortices more effectively maintain anomalous chl-*a* concentrations than leaky eddies (Figure S1). This is illustrated by the following idealized model that describes surface chl-*a* concentration in an eddy (B_{in}):

$$\frac{dB_{in}}{dt} = \mu B_{in} - \Psi(B_{in} - B_{out}). \quad (1)$$

Here B_{out} is the outside-eddy concentration, μ is the biological rate of change (e.g., growth, mortality, photoacclimation) in the eddy, and Ψ is the lateral fluid exchange rate at the eddy boundary. Chl-*a* concentrations increase inside an eddy when $\mu B_{in} > \Psi(B_{in} - B_{out})$. A coherent eddy minimizes Ψ over the timescale of interest. Thus, $\frac{dB_{in}}{dt}$ will be greater in a coherent eddy than in a dispersive eddy with the same μ and B_{out} , resulting in relatively higher chl-*a*. Our analysis of two decades of satellite data in the NPSG indeed reveals “hot spots” of chlorophyll (Calil & Richards, 2010) in Lagrangian coherent eddies and we uncover regional and seasonal differences in the biological signature of eddy trapping.

2 Materials and Methods

The domain includes 2000-2019 and the region 15-30°N, 180-230°. The spatial bounds reduce the degrees of freedom introduced by large-scale environmental variability from the ultra-oligotrophic western NPSG, Transition Zone Chlorophyll Front (Glover et al., 1994), California Current System, and equatorial currents (Figure S2). Moreover, focusing on a small area afforded a comprehensive evaluation of sub-regional and seasonal patterns. We used CMEMS 1/4° daily satellite geostrophic current and SLA data for eddy identification. 8-day average satellite chl-*a* data were obtained from OC-CCI with a spatial resolution of 4km at the equator (Sathyendranath et al., 2019).

2.1 Eddy Atlases

We used the OceanEddies software to generate an Eulerian eddy atlas from daily SLA (Faghmous et al., 2015). The algorithm identifies an eddy boundary as the outermost closed contour containing a single SLA extremum and tracks features through time. We required eddies to have a minimum lifetime of 32 days and contain at least twelve 1/4° grid cells. The smallest SLA eddy has an area of 8,048km² with a radius ≈ 50 km, consistent with the Rossby radius of deformation in the region of interest (Chelton et al., 1998). We set the eddy disappearance parameter to 3 days to account for noise in the data and prevent prematurely “killing” an eddy. We reduced the temporal resolution of the SLA atlas to an 8-day frequency for the ensuing analysis. In total, we tracked 6,846 SLA eddies (52,553 polygons), including 3,322 anticyclones characterized by SLA maxima and 3,524 cyclones by SLA minima.

Haller et al. (2016) introduced the Lagrangian Averaged Vorticity Deviation (LAVD), a measure of the integrated vorticity of a Lagrangian particle over a timescale of interest. An LAVD field is produced by mapping the LAVD for a grid of Lagrangian particles at their initialization locations. A fluid set in rigid-body rotation is identified as a closed contour surrounding a local maximum in the LAVD field, referred to as a Rotationally Coherent Lagrangian Vortex (RCLV) (Haller et al., 2016; Tarshish et al., 2018). Specifically tailored to biogeochemical applications, Jones-Kellett and Follows (*in review*, 2023) identified and tracked 32-day RCLVs in the NPSG at an 8-day resolution using backward-in-time particle simulations synchronized with the OC-CCI 8-day chl-*a* product (Figure S3). The atlas follows RCLVs from age 32 days and onward. Here, we expanded the dataset to capture RCLV genesis because young eddies are associated with biological anomalies (Gaube et al., 2013). To do so, we initialized Lagrangian particles in 32-day-old RCLVs and tracked them backward-in-time with the OceanParcels software (Delandmeter & van Sebille, 2019). At each 8-day “timestep” (ages 24, 16, and 8), we drew closed contours to encompass the particle set (Figure S4). The atlas contains 11,855 tracked RCLVs (75,445 polygons), including 5,592 anticyclones characterized by a negative sign of relative vorticity and 6,263 cyclones by a positive sign.

2.2 Chlorophyll Anomalies

We categorized each pixel from the satellite chl-*a* fields as background (i.e., outside-eddy) or inside an eddy. Some, though not all SLA eddies overlap with an RCLV, and vice versa. Thus, the in-eddy pixels are within an SLA eddy, RCLV, or both. We refer to the pixels inside an SLA eddy boundary but not an RCLV as “SLA excluding RCLV” (Figure S5). This includes the most dispersive regions of the eddy. The “SLA eddy” category includes all pixels within the eddy boundaries irrespective of whether it contains an RCLV.

The climatological chl-*a* anomaly is a temporal metric defined

$$\delta c_{clim}(x, y, t) = c(x, y, t) - \frac{1}{M} \sum_{t'=0}^M c(x, y, t') \quad (2)$$

where $c(x, y, t)$ is the chl-*a* at location (x, y) and time t . $\frac{1}{M} \sum_{t'=0}^M c(x, y, t')$ describes the 2000-2019 mean chl-*a* in the month corresponding to the date t (i.e., the monthly climatology; Figure S6). A positive δc_{clim} indicates that chl-*a* is higher than average for that location and month. We used δc_{clim} to identify changes in chl-*a* related to the mesoscale activity that were distinct from the seasonal cycle.

We define the relative difference in the eddy and background probability density distributions (PDD) of δc_{clim} as

$$f(\delta c_{clim}) = \frac{p_E(\delta c_{clim}) - p_B(\delta c_{clim})}{p_B(\delta c_{clim})} \quad (3)$$

where $p_E(\delta c_{clim})$ is the PDD of the climatological chl-*a* anomalies in an eddy type and $p_B(\delta c_{clim})$ is the PDD of anomalies in the background ocean. $f(\delta c_{clim})$ is interpreted as the likelihood of observing a given chlorophyll anomaly in the eddy type compared to the background. For example, $f(\delta c_{clim}) > 0$ means the value of δc_{clim} is more likely to be observed in an eddy than outside an eddy.

The local chl-*a* anomaly is a spatial metric defined

$$\delta c_{loc} = \frac{1}{A_{in}} \oint_I c(x, y) dI - \frac{1}{A_{out}} \oint_O c(x, y) dO. \quad (4)$$

I is the eddy polygon with area A_{in} and O is the “donut” polygon from the eddy boundary to double the eddy radius with area A_{out} . Thus, $\frac{1}{A_{in}} \oint_I c(x, y) dI$ is the average chl-*a* inside the eddy, and $\frac{1}{A_{out}} \oint_O c(x, y) dO$ is the average in the immediate surroundings

Figure 1. Probability density distributions (PDD) of the climatological chl-*a* anomalies (δc_{clim} ; Equation 2) in (a) anticyclones and (c) cyclones from the 1 – 99% quantiles. The dotted gray lines depict the quantiles of the background distribution, and the dots show the equivalent quantiles for each eddy category. $f(\delta c_{clim})$ is the relative difference in the eddy PDD from the background PDD (Equation 3) for (b) anticyclones and (d) cyclones.

of the eddy. A positive δc_{loc} indicates that the mean chl-*a* concentration in the eddy is higher than surrounding waters.

3 Results

We address the hypothesis that coherent, isolated eddies will maintain anomalous chl-*a* longer than their dispersive counterparts. First, we address the cumulative impacts of eddy trapping. Next, we examine seasonal and sub-regional differences in the biological signature of eddy coherency.

3.1 Cumulative Effect of Eddy Trapping

Cumulatively, surface chl-*a* is higher per unit area in RCLVs than in SLA eddies for both polarities (Table S1). On average, there is more surface chl-*a* in anticyclones than in the background and less in cyclones. Figure 1 shows the probability density distributions of the chl-*a* anomaly relative to the local, seasonal climatology (δc_{clim} ; Equation 2) for anticyclones (a) and cyclones (c). The quantiles of the distributions (indicated by the dots) show a consistent shift toward anomalously high chl-*a* in RCLVs (Figure 1a,c). An exception is the 99% quantile for anticyclones, which is lower than the background. This indicates that positive anomalies are more likely to occur in anticyclonic eddies than in the background ($f > 0$; Equation 3) except at extremely high δc_{clim} (Figure 1b). Coherent cyclones have $f > 0$ for all positive δc_{clim} (Figure 1d). Conversely, cyclonic SLA eddies have positive anomalies less frequently. 21% of chl-*a* in anticyclonic SLA eddies (Table S2) and 23% in cyclonic SLA eddies (Table S3) are also contained within an RCLV. We isolate the leakiest eddy zones when excluding RCLV-associated contri-

butions (“SLA excluding RCLVs” in Figure 1). Fewer positive chl-*a* anomalies are attributed to these zones in both polarities. Eddies are less likely than the background to have negative chl-*a* except for low-magnitude anomalies in cyclones.

3.2 Regional and Seasonal Subdomains

We examined the distributions of δc_{clim} seasonally and regionally to explore variations in how eddy trapping shapes chl-*a* in the NPSG. We determined mesoscale-driven subdomains by the eddy polarity probability (P) (Chaigneau et al., 2009), defined

$$P(x, y) = \frac{F_A(x, y) - F_C(x, y)}{F_A(x, y) + F_C(x, y)}. \quad (5)$$

$F_A(x, y)$ ($F_C(x, y)$) is the number of times the pixel at location (x, y) was inside an anticyclone (cyclone) from 2000-2019. Anticyclonic eddy polarity is more frequent than cyclonic when $P > 0$. Figure 2a depicts the geographic distribution of P for RCLVs, revealing more anticyclonic activity north of 23°N, cyclonic domination to the southeast of Hawai‘i, and Lee eddy signatures to the west.

There are distinctive chl-*a* signatures between northern and southeastern eddies (Figure 2). In the north, cyclones are less likely than the background to have positive δc_{clim} in all seasons except the summer. Northern cyclones are more likely to have a negative δc_{clim} than the background in winter and fall when domain-average chl-*a* concentrations are at the annual maximum (Figure S6, S7). According to Equation 1, a decrease in chl-*a* concentration (B_{in}) may occur when $\mu B_{in} < \Psi(B_{in} - B_{out})$. In an RCLV where Ψ is minimized, it is likely that a low population growth rate, μ , results in lower chl-*a*. For example, low nutrient supply rates may decrease growth rates, mortality may increase, or the cellular chlorophyll-to-carbon ratio can decrease due to increased light availability (Geider, 1987; MacIntyre et al., 2000). Northern anticyclones exhibit nearly opposite signatures than cyclones, with $f > 0$ for positive δc_{clim} (except for extreme anomalies) in fall and winter. Anticyclonic RCLVs (and not SLA eddies) are likelier to have a negative chl-*a* anomaly relative to the summer and fall background. Leaky anticyclones uniquely have $f > 0$ for highly positive δc_{clim} in the summer when mixing with surrounding chl-*a* elevated waters (high Ψ and high B_{out}) may increase concentrations inside SLA anticyclones.

In the southeast province, the distributions of δc_{clim} in cyclones are inordinately different from that of the north. All types of cyclones have $f < 0$ for negative δc_{clim} year-round, suggesting cyclones in this region enhance chl-*a*. In the fall and winter, cyclonic RCLVs are likelier to have a positive δc_{clim} than the background and SLA eddies. Because the chl-*a* signatures of cyclonic SLA eddies excluding RCLVs are like the background, positive anomalies in cyclonic SLA eddies are mostly contained within nested RCLVs. Thus, eddy trapping plays a significant role in the elevated chl-*a* in cyclones of the southeast province. Anticyclones in the southeast have $f > 0$ for low magnitude positive δc_{clim} in the winter and spring. The distributions of δc_{clim} differ between RCLVs and SLA anticyclones during these seasons, suggesting that eddy trapping plays a distinctive role. Anticyclones are more likely than the background to host negative δc_{clim} in the fall. Anticyclones are less prevalent in the southeast province, so these observations play a small role in the cumulative effect in the gyre.

In summary, there are latitudinal biophysical differences within the NPSG. Anticyclones have high chl-*a* anomalies in the north during fall and winter and eddy trapping plays a minimal role in altering chl-*a* concentrations. In the southeast, cyclones foster high chl-*a* in fall and winter and chl-*a* is significantly higher in Lagrangian coherent vortices than in Eulerian eddies.

Figure 2. (a) RCLV polarity probability. Red (blue) indicates that anticyclones (cyclones) are more common at the location. The black lines delineate mesoscale-driven provinces. (b-i) The relative difference in the probability density distribution of the climatological chl-*a* anomaly from the background ($f(\delta_{C_{lim}})$) for each eddy type. Each row corresponds with a season (winter includes December to February). Figures S8 and S9 show the underlying probability density distributions.

Figure 3. (a) Schematic of the currents that sustain the Hawaiian Lee eddies. The region dominated by cyclones (anticyclones) is blue (red). Two RCLV boundaries plotted every 16 days show the common propagation pathways westward from the islands. (b-f) The relative difference in probability density distributions of the climatological chl-*a* anomaly from the background ($f(\delta c_{clim})$). Note that the y-axis differs from Figure 2 to accommodate larger values. Figure S10 depicts the underlying probability density distributions. Panel (c) includes the same information as (b) with a different y-axis to expose the curves.

3.3 Hawaiian Lee Eddies

The ‘‘Hawaiian Lee eddies’’ are large, long-lived features formed in the Lee of the Hawaiian Islands (Figure 3a). The shear instability between the eastward-flowing Hawaiian Lee Countercurrent and the westward-flowing North Equatorial Current generates anticyclones (Calil et al., 2008; Yoshida et al., 2010; Y. Liu et al., 2012). A wind stress curl anomaly associated with blocking trade winds by the islands produces cyclones (Lumpkin, 1998; Yoshida et al., 2010). The Hawaiian Lee Countercurrent to the south and the westward-flowing Hawaiian Lee Current to the north sustain the cyclonic vorticity.

RCLVs and SLA eddies of both polarities have $f > 0$ for positive δc_{clim} year-round (Figure 3b-f). Trapping also plays a significant role in the chl-*a* signature of the Hawaiian Lee eddies. RCLVs have more positive chl-*a* anomalies than SLA eddies and the background ocean. We found a similar chl-*a* response to cyclonic and anticyclonic RCLVs in the summer and fall. However, anticyclones are more likely to have positive anomalies than cyclones in the winter and spring. Even the leakiest anticyclonic features (i.e., SLA excluding RCLVs) host positive δc_{clim} during these seasons. In the winter, anticyclonic RCLVs can be up to 15 times more likely than the background to have a positive δc_{clim} , whereas cyclonic RCLVs are up to 2 times as likely.

3.4 Chlorophyll Evolution of Long-lived Eddies

The Lagrangian eddy atlas enables the examination of chl-*a* patches as they evolve through time in quasi-isolated systems. Accordingly, we analyzed the in-eddy chl-*a* anomaly compared to the immediate surroundings, δc_{loc} (Equation 4), as a function of age for 245 RCLVs (109 anticyclones, 136 cyclones; Figure 4) that maintained coherency for 150 or more days. Figure S11 illustrates the westward propagation of these features. The magnitudes of δc_{loc} complement the results of Sections 3.2 and 3.3. For example, RCLVs in the north minimally alter chl-*a* compared to their surroundings except for wintertime anticyclones. In that case, the largest anomalies occur early in the lifetime. Cyclonic RCLVs foster heightened chl-*a* that declines with eddy age in the winter and fall in the southeast. Hawaiian Lee RCLVs dramatically localize chl-*a*, and this is the only domain where RCLVs have increasing δc_{loc} with eddy age. The results show that there is not a uniform slope of change in chl-*a* as a function of eddy age. Rather, chl-*a* evolves in coherent eddies depending on the region, season, and eddy polarity.

We apply the model of chl-*a* concentrations in eddies (Equation 1) to interpret the rate of change in δc_{loc} with RCLV age such that

$$\frac{d}{dt}(\delta c_{loc}) = \frac{dB_{in}}{dt} - \frac{dB_{out}}{dt}. \quad (6)$$

Consider the case where μ is equivalent in and out of the eddy. This is likeliest to occur toward the end of an eddy’s life when the effects of eddy pumping and Ekman pumping are reduced (Huang et al., 2017). The change in chl-*a* concentration outside of the eddy is

$$\frac{dB_{out}}{dt} = \mu B_{out} + \Psi \left(\frac{A_{in}}{A_{out}} \right) (B_{in} - B_{out}). \quad (7)$$

Substituting Equations 1 and 7 into Equation 6,

$$\frac{d}{dt}(\delta c_{loc}) = \left(\mu - \frac{4}{3}\Psi \right) (B_{in} - B_{out}) \quad (8)$$

for a circular eddy ($A_{in} = \pi r^2$). Equation 8 suggests that a larger Ψ (i.e., a leakier boundary) will cause elevated chl-*a* in an eddy to dilute more rapidly (Text S1). A positive $\frac{d}{dt}(\delta c_{loc})$ is sustained when $\mu > \frac{4\Psi}{3}$ and $B_{in} > B_{out}$. Since chl-*a* is anomalously high in Hawaiian Lee RCLVs, these features are most likely to meet both of these conditions, as exhibited in Figure 4. In most cases, however, an eddy-associated chl-*a* anomaly will decay via lateral dilution without sustained growth and low death rates.

Figure 4. Local chl-*a* anomalies (δc_{loc}) in RCLVs with lifespans of 150+ days. Each column corresponds to a mesoscale-driven province and each row with the season. Cyclonic (anticyclonic) eddies are in blue (red). The solid lines show the median δc_{loc} by RCLV age, and the shaded areas are the ranges of the 25% to 75% quantiles.

4 Discussion

Harnessing the temporal and spatial coverage of satellite observations, we measured the effects of mesoscale eddy trapping on chl-*a* concentrations in the NPSG. We compared Lagrangian (RCLV) and Eulerian (SLA) eddy atlases to distinguish signatures of chl-*a* in coherent eddies, dispersive eddies, and the background. Positive climatological chl-*a* anomalies are observed more in RCLVs than in SLA eddies or outside-eddy waters of the NPSG (Figure 1). However, trapping does not significantly shape the biological response to eddies everywhere. In northern latitudes ($> 23^{\circ}\text{N}$), the chl-*a* signatures of coherent and leaky eddies are nearly indistinguishable (Figure 2). On the other hand, eddy trapping enhances chl-*a* signatures in the southeast ($< 23^{\circ}\text{N}$) to varying amounts that depend on season and polarity. The response to coherency is strongest overall in the Hawaiian Lee eddies, where chl-*a* is enhanced year-round in RCLVs (Figure 3). The region and season also affect the slope of the chl-*a* anomaly as a function of the eddy age, which can be positive, negative, or constant (Figure 4).

Chl-*a* in the NPSG is more highly concentrated on average in anticyclonic RCLVs and SLA eddies than in cyclones and the background ocean (Table S1). In contrast, He et al. (2022) found anomalously high chlorophyll in Lagrangian coherent cyclones and low chlorophyll in anticyclones of the Northwest Pacific. Their results reflect particular biological signatures of warm and cold-core rings formed in the Kuroshio Current that translate into the gyre. Localized eddy features in the central gyre are far from such strong environmental gradients. In our study, we note that anticyclones are over-represented in the north (Table S2), the largest province within the domain, where they tend to elevate chl-*a*. Table S3 shows that cyclones are highly present in both the north and south-

east provinces, where chl-*a* anomalies in cyclones can be opposing. Our findings emphasize the complexity in the regional variations of the chl-*a* response to eddies of different polarities (Gaube et al., 2014). We also show definitive regional variations in the relationships of chl-*a* with eddy trapping.

A broad interpretation of the changes in chl-*a* at the mesoscale remains enigmatic. While Dufois et al. (2016) suggests that phytoplankton in subtropical gyre anticyclones are more productive in winter, others argue that changes in the chlorophyll-to-carbon ratio due to photoacclimation drive the signature (He et al., 2021). However, higher fish catch occurs in anticyclones compared to cyclones around the Hawaiian Islands (Arostegui et al., 2022), which may suggest that increased phytoplankton productivity supports higher trophic levels. Changes in chl-*a* may also indicate a change in community structure. Waga et al. (2019) used a size structure ocean color algorithm to infer that anticyclones in subtropical gyres support larger phytoplankton cells than cyclonic eddies. Eddy trapping may act to further alter community structure by separating populations and sheltering them from competition (Bracco et al., 2000). Interpreting whether the underlying phytoplankton communities differ in RCLVs and SLA eddies would require targeted in situ observations that could provide valuable insight into the observed relationships between eddies and chl-*a*.

Although satellites are the only ocean observing systems that obtain nearly full spatial coverage within days, a fundamental limitation is the restriction to the surface. The biological response to eddies at depth may differ from the surface signature (Huang & Xu, 2018; Zhao et al., 2021). Eddies affect subsurface chl-*a* in the NPSG by altering the depth of the deep chlorophyll maximum (Gaube et al., 2019; Xiu & Chai, 2020) and the vertical community structure (Olaizola et al., 1993; Brown et al., 2008; Fong et al., 2008; Barone et al., 2019). Here we focused on lateral biophysical interactions, but vertical mixing tied to the wind stress, heat exchange, and changes in the mixed layer depth will also influence the surface chl-*a* concentration (Gaube et al., 2013; McGillicuddy Jr, 2016). Moreover, the size of Lagrangian coherent boundaries may differ with depth (Nencioli et al., 2008; Ntaganou et al., 2023). Another limitation of satellite chl-*a* observations is missing data from cloud coverage including storms that can stimulate phytoplankton blooms in eddies (X. Liu et al., 2009; Shang et al., 2015; Villar et al., 2015; Chacko, 2017; Mikaelyan et al., 2020). Some of these limitations may be overcome by co-locating the bounds of RCLVs with autonomous vehicles and targeted shipboard observations of eddies, a promising avenue of future exploration.

Phytoplankton have a complex relationship with mesoscale eddy activity and respond depending on the polarity, trapping strength, location, season, and eddy age. By tracking Lagrangian coherent eddy boundaries from two decades of data in the NPSG, we show that eddy trapping can locally intensify chl-*a*. On the other hand, phytoplankton blooms generated inside SLA eddies may be quickly laterally advected and thus miss being associated with features once they leave the Eulerian bounds. It is important to consider dispersive eddy-associated perturbations since vertical mixing associated with submesoscale filaments stimulates primary production on eddy edges (Mahadevan, 2016; Guo et al., 2019) and lateral dilution of a chl-*a* patch can enhance the anomaly (Ser-Giacomi et al., 2023; Lehahn et al., 2017). We encourage future studies to employ Lagrangian metrics of coherency to support interpretations of biophysical interactions in eddies.

Open Research Section

This study has been conducted using E.U. Copernicus Marine Service Information, namely the Level 4, 1/4° SLA and geostrophic velocity gridded global ocean dataset (Version 008_047) distributed at <https://doi.org/10.48670/moi-00148>. 8-day average chl-*a* is produced by OC-CCI (Version 6.0 used here) and distributed by the European Space Agency at <https://www.oceancolour.org/> (Sathyendranath et al., 2019). The OceanEd-

dies MATLAB software that detects and tracks Eulerian SLA eddy contours is available at <https://github.com/ifrenger/OceanEddies> (Faghmous et al., 2015). The Ocean-Parcels v2.0 Python package used to run Lagrangian particle simulations is available at <https://oceanparcels.org/index.html> (Delandmeter & van Sebille, 2019). All figures were created with Matplotlib 3.3.4 (Caswell et al., 2021; Hunter, 2007), available under the Matplotlib license at <https://matplotlib.org/>.

The Python software developed for this study is available at <https://github.com/lexi-jones/RCLVatlas> (Jones-Kellett, 2023b). The code includes a pipeline to run Ocean-Parcels on Copernicus data, a custom kernel to calculate the relative vorticity along particle trajectories, and an RCLV tracking algorithm. The Jupyter notebook script https://github.com/lexi-jones/RCLVatlas/blob/main/example_usage.ipynb includes an example usage code for the software. The NPSG RCLV dataset is publicly available, distributed by Simons CMAP at https://simonscmr.com/catalog/datasets/RCLV_atlas (Jones-Kellett, 2023a).

Acknowledgments

We are grateful for support from the Simons Foundation (Simons Collaboration on Ocean Processes and Ecology, Award 329108, M.J.F.; CBIOMES, Award 549931, M.J.F.).
