38 **Key Points:**

39 - A dacitic unit was recovered in early Eocene sediments on the Vøring margin during
40 International Ocean Discovery Program Expedition 396.

41 - The dacite was formed by upper crustal anatexis at 54.6 ± 1.1 Ma, postdating the
42 Paleocene-Eocene Thermal Maximum.

43 - The dacite is evidence for a pre-breakup phase associated with significant continental
44 lithospheric extension.

Abstract

45

46 While basaltic volcanism is dominate during rifting and continental breakup, felsic magmatism

47 may also comprise important components of some rift margins. During International Ocean

48 Discovery Program (IODP) Expedition 396 on the continental margin of Norway, a graphite-

49 garnet-cordierite bearing dacitic, pyroclastic unit was recovered within early Eocene sediments

50 on Mimir High (Site U1570), a marginal high on the Vøring transform margin. Here, we present

51 a comprehensive textural, mineralogical, and petrological study of the dacite in order to assess its

52 melting origin and emplacement. The major mineral phases (garnet, cordierite, quartz,

53 plagioclase, alkali feldspar) are hosted in a fresh rhyolitic, highly vesicular, glassy matrix, locally

54 mingled with sediments. The xenocrystic major element chemistry of garnet and cordierite, the

55 presence of zircon inclusions with inherited cores, and thermobarometric calculations all support

56 a crustal metapelite origin. While most magma-rich margin models favor crustal anatexis in the

57 lower crust, thermobarometric calculations performed here show that the dacite was produced at

58 upper-crustal depths (< 5 kbar) and high temperature (750–800 °C) with up to 3 wt% water

59 content. In situ U-Pb analyses on zircon inclusions give a magmatic age of 54.6 ± 1.1 Ma,

60 revealing the emplacement of the dacite post-dates the Paleocene-Eocene Thermal Maximum

61 (PETM). Our results suggest that the opening of the North Atlantic was associated with a phase

62 of low-pressure, high-temperature crustal melting at the onset of the main phase of magmatism.

63

Plain Language Summary

65 Fifty-six million years ago, the continents were beginning the final phase of their journey to their

66 current configuration. This included the rifting and formation of the Northeast Atlantic Ocean,

67 known in particular for the excess amounts of magmatic activity that accompanied continental

68 breakup. The International Ocean Discovery Program organized Expedition 396 to collect

69 volcanic and sedimentary rocks deposited during this time off the coast of present-day Norway to

70 investigate the cause of the excess magmatism and its potential implications for the global

71 climate. While sampling sediments on the expedition, an unexpected volcanic unit, a garnet-

72 cordierite, glassy dacite, was recovered. To determine the origin and emplacement of this unit we

73 combined multiple methods (petrography, stratigraphy, thermodynamic calculations,

74 geochronology, in site compositional analyses) and showed that the unit was produced by

75 melting of the upper continental crust at depth during the rifting process and likely later

76 emplaced as a pyroclastic flow in shallow water. Our results demonstrate that the rifting process

77 in the Northeast Atlantic included a long and intense period of continental lithospheric thinning.

78 This research provides evidence needed to reconstruct the evolution of the North Atlantic Ocean

79 and associated magma production.

1 Introduction

81 The North Atlantic Igneous Province (NAIP) is an estimated $6–10\times10^6\,km^3$ of magma

82 that was emplaced during the Paleogene (64–35 Ma; Storey et al., 2007). Much of this volume

83 was emplaced 56 to 54 million years ago (Ma), which coincides with the opening of the North

84 Atlantic, which began around 56 Ma (Saunders et al., 2007; Horni et al., 2017; Westerhold et al.

85 2020; Planke et al., 2023a). In the NE Atlantic, on the mid-Norwegian rift margin, NAIP

86 material is present as successions of voluminous extrusive basalt flows, including seaward

87 dipping reflectors (SDRs), magmatic intrusions within the continental crust and associated

88 sedimentary basins, and high-velocity bodies underlying the continent-ocean boundary (COB) at

89 the base of the continental crust which, at least in the distal margin, are interpreted as a magmatic

90 underplate (Fig. 1; Berndt et al., 2001; Mjelde et al., 2005; Planke et al. 2005; Planke et al.,

91 2023a; Svensen et al.. 2004). Passive rift margins whose volume of magmatic production and

92 volcanic activity cannot be explained by decompression melting of the sub-lithosphere at

93 ambient mantle temperature, like the mid-Norwegian margin, are classified as excess magmatic

94 margins (Lu & Huismans, 2001), or volcanic rifted margins.

95 Excess magmatism at volcanic margins was first attributed to active rifting (as opposed to

96 passive rifting in non-volcanic margins; Celal Sengör & Burke, 1978). In a purely active model,

97 a hot mantle (related, for example, to the presence of a mantle plume) thermally erodes the

98 bottom of the lithosphere (Fleitout et al., 1896) and results in two stages of rifting: (1) flood

99 basalt stage, coeval with very small crustal extension, and (2) a break-up stage associated with

100 the volcanic margin formation (Courtillot et al., 1999). During active rifting, regional uplift

101 predates and accompanies the volcanic margin development (e.g. Clift et al., 1998; White &

102 Lovell, 1997). However, the purely active upwelling model is limited by evidence that many

103 volcanic rifted margins are associated with regions that have been previously subjected to far-

104 field extension (White & McKensie, 1989). This relationship suggests that prior extension may

105   facilitate volcanic activity and that deep mantle plumes may not be required to explain all cases

106   of excess magmatism (e.g. Hill, 1991; White & McKensie, 1989). However, it is important to

107   highlight that volcanic margins can also develop in areas that were not subjected to significant

108   lithospheric stretching leading up to the flood basalt stage (e.g. in Afar; Courtillot et al. 1999).

109   While accurate timing of the initiation and end of continental rifting, of the peak of magmatic

110   activity, and of the main continental break-up phase is crucial to refine models of margin

111   development, the causality and timing between rifting and excess magmatism is still poorly

112   constrained.

113
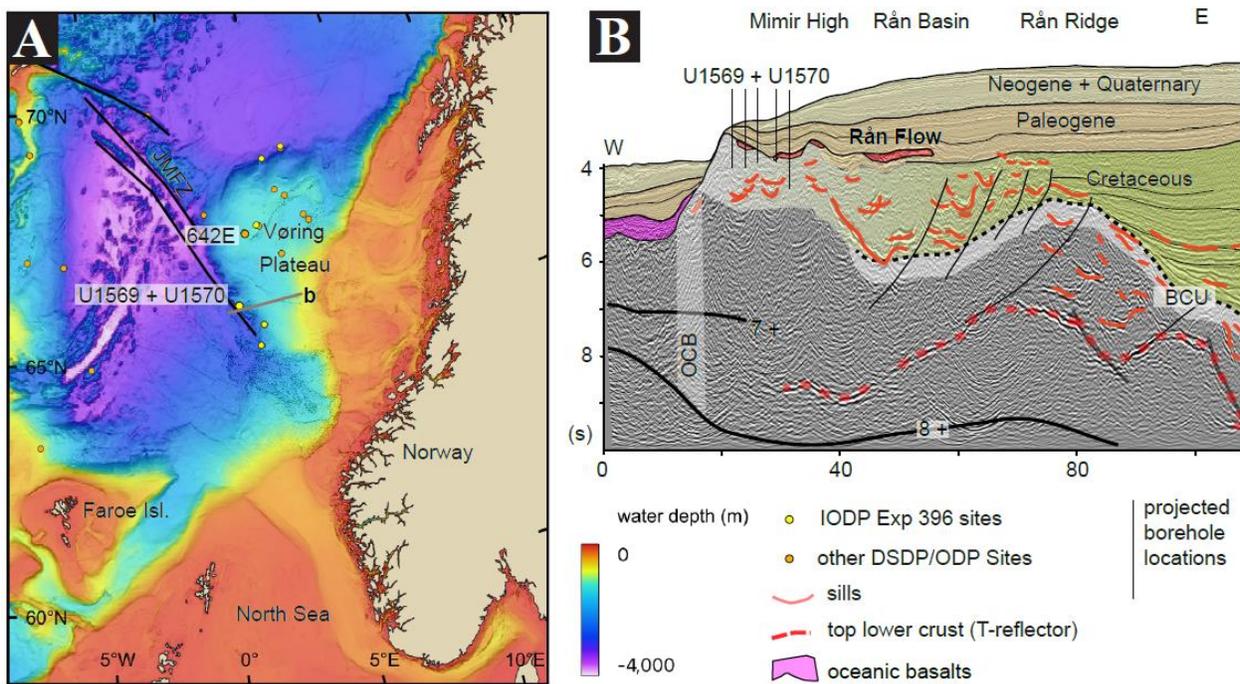

114   **Figure 1**. (a) Bathymetry map showing relative locations for IODP Expedition 396 (yellow

115   circles), and for other DSDP/ODP sites (orange circles). The brown line shows the location of

116   the seismic profile in (b). (b) Interpreted seismic section along Mimir High and the Rån Basin.

117   The 7+ km/s and T-reflection (TR) are interpreted as the top of the lower crustal body (LCB), the

118   8+ km/s as the seismic Moho, and BCU, this Base Cretaceous Unconformity. Adapted from

119   Abdelmalak et al. (2017).

120   During the recent International Ocean Discovery Program (IODP) Expedition 396, a

121   dacitic unit was recovered in lower Eocene sediments deposited on the Mimir High (Fig. 1A;

122   Planke et al., 2023b). Mimir High is a marginal high adjacent to the Vøring transform margin,

123   the landward extension of the Jan Mayen Fracture Zone that segments the mid-Norwegian rift

124 margin. Dacite flows in oceanic or transitional regimes outside of volcanic arcs are unusual but

125 not unique. For instance, they have been collected at several locations in the NAIP, including in

126 Well 163/6-1A in the northern Rockall Trough (Morton et al., 1988a), in Well 209/3-1 in the

127 Faroe-Shetland Basin (Kanaris-Sotiriou et al. 1993), in Hole 642E on the Vøring Plateau from

128 Ocean Drilling Program (ODP) Leg 104 (Fig. 1; Eldholm et al., 1987; Viereck et al., 1988), and

129 on the southeast Greenland margin (Larsen et al., 1995). Garnet and cordierite-bearing dacitic

130 flows have also been reported in the Neogene Volcanic Province (NVP) in SE Spain that are

131 associated with the opening of the Alborán Domain in the late Tertiary (Platt et al., 1998; Vissers

132 et al., 1995). Dacitic flows have previously been interpreted as being products of crustal melting

133 at various depths, with the units recovered in the NE Atlantic interpreted as produced in shallow

134 magma chambers (Eldholm et al., 1989) and the units from SE Greenland as derived from

135 magma differentiation and crustal contamination in the lower crust (e.g., Fitton et al., 1995).

136 Dacites previously collected in the NE Atlantic are peraluminous, suggesting they were

137 generated through the melting or assimilation of pelitic sediments or metapelitic rocks. However,

138 previously recovered units have experienced varying degrees of alteration (e.g., Abdelmalak et

139 al., 2016; Morton et al., 1988) and, to our knowledge, no thermobarometric calculations were

140 performed to constrain the origin of these rocks. Here, we use petrographic analyses, major and

141 trace element compositions of mineral phases, in-situ U-Pb zircon dating, and thermodynamic

142 modeling to discuss the petrogenesis and emplacement of the dacite in the context of the

143 emplacement of the NAIP and explore the geodynamic implications for the development of the

144 Vøring margin.

145 1.1 Geologic setting

146 Mimir High (Fig. 1) is a marginal high on the continent side of the continent-ocean

147 boundary of the Vøring transform margin. This margin is characterized by diminished extrusive

148 volcanism relative to the adjacent rifted margin segments of the Vøring and Møre basins (Berndt

149 et al., 2001). The absence of basalt cover makes the Mimir High an exceptional place to study

150 the stratigraphic successions and effects of sill intrusions (Planke et al., 2023). In fact, seismic

151 interpretation suggests that the Mimir High was a depocenter during the Eocene, which makes it

152 an ideal candidate for recovering expanded Paleocene–Eocene sedimentary sections. During

153 Expedition 396, a transect of five boreholes was drilled along the Mimir High with the intention

154 of forming a composite ribbon core through most the Paleocene and Eocene strata (Fig. 2). In

155 two of these boreholes (U1570A and D), the early Eocene sediments hosted a discrete (<10 m

156 thick) glassy, garnet-cordierite-graphite dacitic igneous unit (Planke et al., 2023).

157 The dacite was recovered from between 146.84 and 151.96 meters below surface (mbsf)

158 in Hole U1570A and between 100.75 and 110.91 mbsf in Hole U1570D (Fig. 2). The contact

159 between the base of the dacite and dark gray and grayish-brown ash-rich siltstone was recovered

160 in the cores from both boreholes. This basal contact is 8 and 9 m above the Paleocene–Eocene

161 Thermal Maximum (PETM) interval in holes U1570D and U1570A, respectively (Vickers et al.,

162 2023). Within both holes, the dacitic unit is observed as semi-discrete layers with local peperitic

163 texture and mingling with dark, sand-rich silt with small (2–5 cm) intervals of silt and claystone

164 between them (Fig. 2C). It is overlain by an early Eocene (Ypresian) age dark gray claystone

165 with black ash and intervals of gray limestone. The top contact between the dacite and the early

166 Eocene sediments was also recovered in Hole D (Fig. 2B). While this unit was not encountered

167 in Hole U1569A, millimeter-size garnet grains were recovered in the core catcher of Section

168 U1569A–35R collected at 315.66 mbsf. The location of this section is indicated by an open pink

169 star in Figure 2F.

170

171
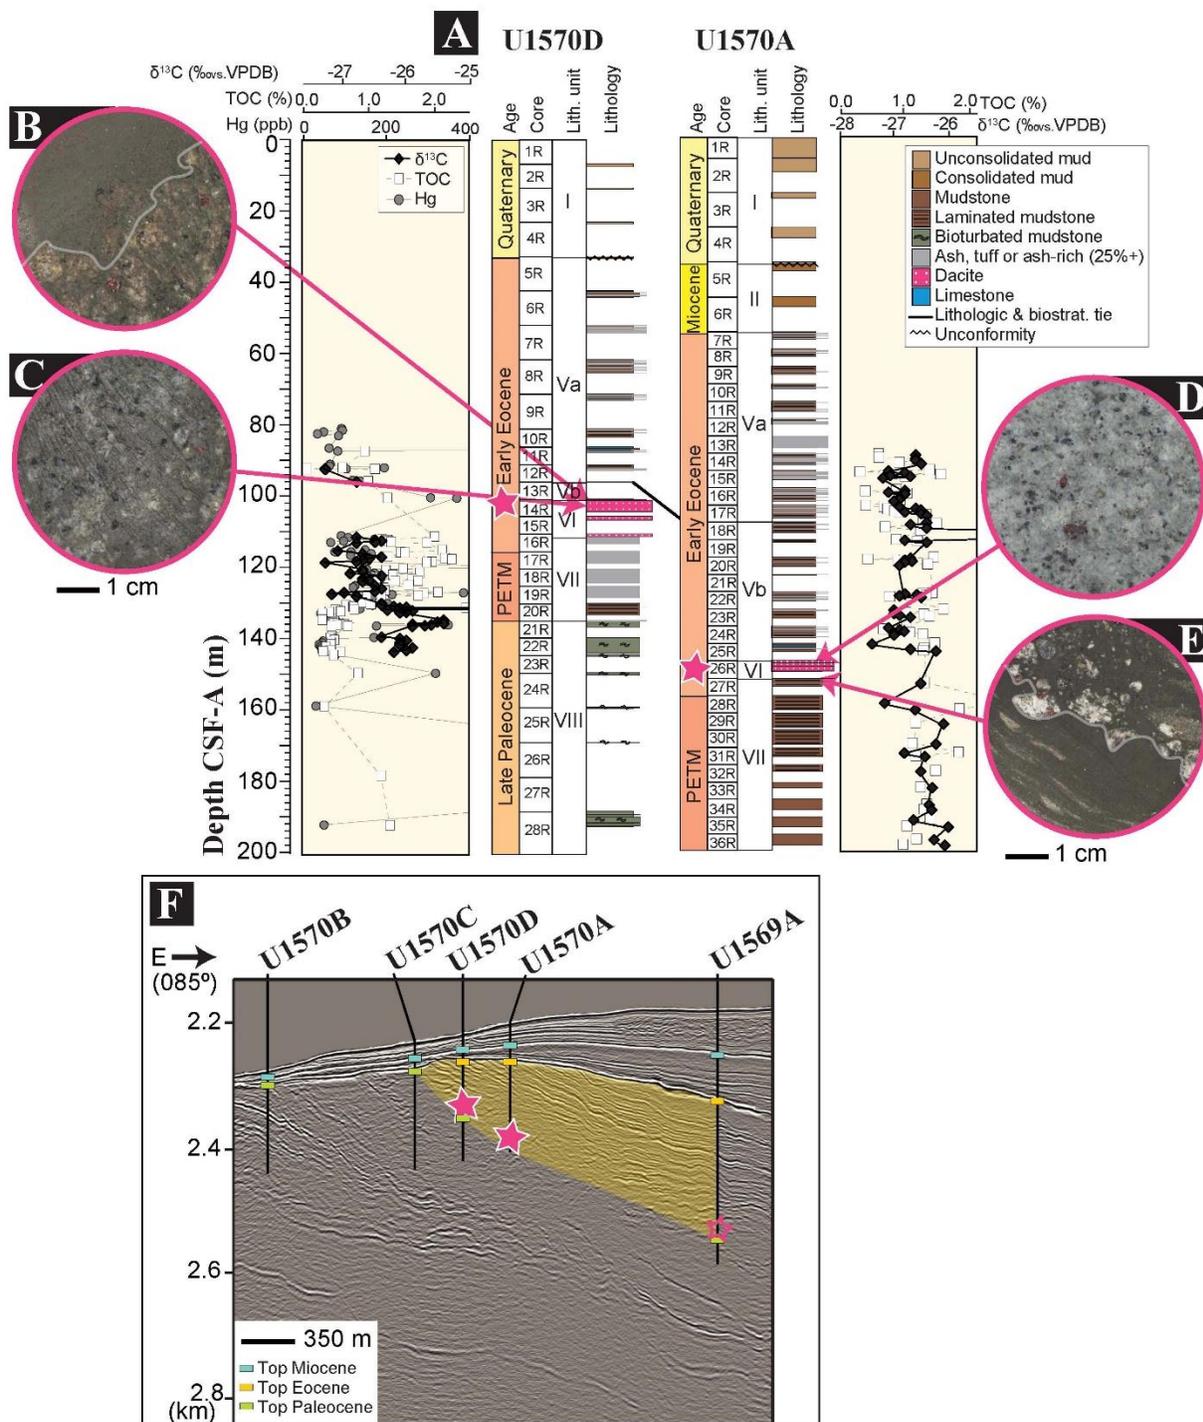

Figure 2. (a) Stratigraphic columns of the boreholes U1570D and U1570A cores modified from
Planke et al. (2023b) and associated TOC, Hg concentrations, and $\delta^{13}C_{org}$ measurements in the
sediments. The dacitic unit is represented in pink with white dots. Large circles show various
facies of the dacitic unit at the locations indicated by arrows in the stratigraphic column. (b)

176   Contact between the layered sediments and the dacite (sample 1570D-14R1-11-18, read as

177   borehole U1570D, core 14, section 1 between 11 and 18 cm), (c) peperitic texture (sample

178   1570D-14R2-7-11), (d) a fresh, unmingled section of dacite (sample 1570A-26R2-51-54), and

179   (e) basalt contact between the dacite and early Eocene sediment below (highlighted with a gray

180   line; sample 1570A-27R1-9-13). The 1cm scale bar refers to all images of the core. (f) The

181   interpreted seismic section at sites U1570 and U1569, adapted from Planke et al. (2023),

182   showing the spatial relationship between the boreholes, geological epochs, and the locations of

183   dacite recovery (pink stars); smaller open pink star is the recovery location of individual garnet

184   grains at site U1569.

185   **2 Methods**

186   2.1 Bulk rock geochemical analyses

187   We analyzed two samples for major and trace element bulk rock concentrations; a

188   representative fresh sample with little to no mixing with sediments (U1570A–26R2–51–54 cm;

189   Fig. 2D) and a sample collected for being representative of mingling textures with the sediments

190   (U1570D–14R2–7–11 cm; Fig. 2C). Sample U1570A-26R2-51-54 major element composition

191   was done using Thermo Scientific ARL X-ray fluorescence (XRF) spectrometer at Institute of

192   Geochemistry, Chinese Academy of Sciences. BHVO-2 and BCR-2 were used as secondary

193   standards. Trace element concentrations were acquired using the Agilent-7900 inductively

194   coupled plasma mass spectrometer (ICP-MS) at Institute of Oceanography, Chinese Academy of

195   Sciences, following procedures of Chen et al. (2017). In brief, ~50 milligrams of the sample

196   were dissolved with an acid mix of double distilled, concentrated $HCl+HNO_3$ and HF in a high-

197   pressure bomb for 15 hours and then re-dissolved with distilled 20% HNO_3 for 2 hours until

198   complete digestion/dissolution. BHVO-2 was used as a secondary standard. Analytical

199   accuracy on secondary standards is better than 5% for all major elements and most trace

200   elements, between 5% and 10% for Li, Cr, Mn, and Cu, and better than 15% for Be, Ti, V, Zn

201   and Ta.

202   Sample U1570D-14R2-7-11 major element composition was analyzed using X-ray

203   fluorescence spectrometry (Rigaku RIX3000) at Niigata University following the analytical

204   method of Takahashi and Shuto (1997), with an optimization for ultramafic rocks. Trace element

205   concentrations were determined using a Yokogawa HP4500 ICP-MS at Niigata University,

206   following the acid digestion method described in Senda et al. (2014). In brief, for each sample,

207   100 mg of material was weighed and placed in a Teflon vial and underwent step-by-step acid

208   treatment with heating until the sample reached complete dissolution. The solution was finally

209   diluted using HNO_3 and an internal standard (^{115}In) and was measured along with secondary

210   standards (BHVO-2, W2a and JB2).Analytical accuracy on secondary standards is better than

211   5% for most elements, between 5 and 10% for Sc, Ga, Sr, Nb, Gd, Dy, Yb, Lu, Hf, and Pb, and

212   12% for Cs.

213   2.2 Sample selection for in situ analysis

214   Fourteen samples of the dacite unit were collected from both Holes U1570A and

215   U1570D. Materials were sampled to include a range of apparent volcanic facies (undisturbed

216   versus higher degrees of sediment mingling). Four thin sections (30 μm thick) were impregnated

217   with blue epoxy to highlight the porosity. The remaining ten samples were cut, polished, and

218   carbon-coated into thick sections (300–1000 μm thick) to minimize potential issues with the

219   fragility of the sample and to facilitate laser ablation analyses.

220   2.3 Scanning electron microscopy and electron microprobe analysis

221   Scanning electron microscope (SEM) images presented in this study were collected using

222   a JEOL JSM-IT300 at the Energy and Geoscience Institute (EGI) at the University of Utah.

223   Major and minor element compositions were acquired using a Cameca SX100 electron

224   microprobe at the University of Utah. A 15 keV beam voltage and 20 nA beam current were used

225   for all analyses. Single spot measurements were used for mineral phases and glass using beam

226   diameters of 5 μm and 10 μm, respectively, and 1–3 spots were analyzed on each large mineral

227   phase. Sodium (Na) and potassium (K) were analyzed first, and a time-dependent intensity (TDI)

228   correction was applied to correct the signal from devolatilization (Nielson & Sigurdsson, 1981;

229   Siivola, 1969). Compositional profiles were also acquired across large (1–4 mm) garnet grains

230   using a 5 μm beam diameter every ~120 μm (individual analysis locations within these profiles

231   were adjusted to avoid cracks and inclusions). On-peak counting times were 10 s for major

232   elements and 20 s for minor elements; half of the on-peak time was used on each of the high and

233   low backgrounds. The following ASTIMEX reference standards were used, Rutile (Ti),

234   Chromite (Cr), Diopside (Ca), Albite (Al, Na, Si), Sanidine (K), Apatite (P), and Sphalerite (S).

235   Additionally, we used synthetic Mn and a Ni olivine provided by George Rossman to calibrate

236   Mn and Ni, and the USNM San Carlos olivine distributed by the Smithsonian Institute (USNM

237   111312/44) to calibrate Fe and Mg. Data were processed using the 'Probe for EMPA (v. 12.7.3)'

238   software and the PAP procedure was used for data reduction (Pouchou & Pichoir, 1991). BHVO-

239   2g and USNM San Carlos olivine 111312/44 were repeatedly analyzed as secondary standards

240   during each analytical session to monitor drift on major and minor elements, but no additional

241   corrections were applied.

242   2.4 Laser ablation inductively coupled plasma mass spectrometry

243   *2.4.1 Trace element analysis of garnet, cordierite, and feldspars*

244   Trace element concentrations in garnet, plagioclase, alkali feldspar, and cordierite were

245   collected using laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS).

246   Analyses were performed at the University of Utah on a Teledyne-Photon Machines Analyte

247   Excite Excimer LA system attached to an Agilent 8900 ICP-MS. The laser carrier and the

248   nebulizer gas flow were 1 L He/min (0.4 L/min cup +0.6 L/min cell and 1.1 L Ar/min,

249   respectively). The first half of the analytical session was run using a fluence of 2.19 J/cm^2, which

250   was later increased to 3.29 J/cm2 in an attempt to reduce shattering observed on quartz grains

251   (see below). We used a laser repetition rate of 10 Hz. We used 40 μm spot analyses, with each

252   analysis preceded by a cleaning shot. Acquisition times were about 50 s. To assess compositional

253   variability, 1–5 analyses were performed per grain. NIST610 and NIST612 were measured every

254   six unknown analyses for a (total n = 23) and used as primary standards for elements with

255   concentrations higher and lower than 100 ppm, respectively. The Si contents, measured by

256   electron microprobe, served as an internal standard. Each element signal was carefully monitored

257   for spikes that may indicate the presence of cracks or inclusions; in this case, the analysis was

258   discarded. We tested the accuracy of each measurement with BHVO-2G, which was acquired

259   every 12 unknown analyses for a total of 10 analyses. Measured concentrations for BHVO-2G

260   are compared with the GeoReM preferred values (Jochum et al. 2005); the relative errors on each

261   trace element contents are reported in Table S1.

262   *2.4.2 Trace element analysis of quartz*

263   For quartz grains, we performed an additional analytical session with a fluence of 7.90

264   J/cm^2, a 5 Hz laser repetition rate, and pre-ablation cleaning spots for 85 μm single spot analyses.

265   These conditions minimized the number of quartz grains shattered by the laser, providing 51

266   quartz analysis from 17 individual grains with good analytical signals. Elements analyzed in

267   quartz are Ti, Li, Na, Al, P, K, Ge, Rb, Sr, Zr, and Ba. NIST610 was used as the primary

268   reference material, measured once every five to eight quartz analyses for a total of 21

269   measurements. The data were processed by normalizing analytical peaks from the mass

270   spectrometer by their ^{28}Si values and converted to ppm using the NIST610 standard values as

271   calibration. NIST612 was used as a secondary standard. Comparison of the mean concentrations

272   from 11 NIST612 analyses with the GeoReM preferred values (Jochum et al. 2011) shows that

273   the relative error on the trace element contents in quartz is 6.7% for Ti and lies between 1.0 and

274   12.1% for the other analyzed elements (Table S1). We also performed six analyses on the

275   reference material San Carlos Olivine NMNH 111312/42 and compared the data with data

276   published in the literature (Lambart et al., 2022). The measured Ti concentration in olivine San

277   Carlos reference material overlaps with the published values inside the two standard deviation

278   (Table S1).

279   *2.4.3 U-Pb zircon analyses*

280   Twenty-five zircon crystals across two samples were located and imaged using

281   backscattered electron and cathodoluminesence (CL) detectors. The BSE and CL images (Fig.

282   S1) guided laser spot placements to minimize any mechanical mixing of chemically and/or

283   isotopically distinct domains and to ensure an analysis of the full range of populations in each

284   sample. Both U-Pb and trace element analyses were performed simultaneously for the two

285   samples by Laser Ablation Split Stream (LASS; Kylander-Clark et al., 2013; Stearns et al., 2020)

286   at the Petrochronology lab of the University of California Santa Barbara. The crystals were

287   ablated using a Photon Machines/Teledyne 193 nm Excimer laser equipped with a two-volume

288   Helex® stage (Eggins et al., 1998) and the ablated material was introduced via He carrier gas to

289   the multi-collector ICP-MS and quadrupole (Q-MS) mass spectrometers to measure uranium,

290   thorium, and lead isotopes and trace elements, respectively. The Nu Plasma multicollector

291   measured ^{238}U, ^{235}U, ^{232}Th, ^{208}Pb, ^{207}Pb, ^{206}Pb, ^{204}Pb, ^{202}Hg and the Agilent 7700X quadrupole

292   measured Zr, Th, U, Si, P, Ti, V, Sr, Y, Nb, Mo, La, Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er,

293   Tm, Yb, Lu, Hf, Ta, and W.

294   A total of 88 unknown analyses on the U1570 dacite's zircons were collected using a 12

295   μm spot size, a 5Hz laser operating frequency, and pre-ablation cleaning shots. A standard

296   sample bracketing method was used, and a series of primary and secondary reference materials

297   were measured, including GJ (608.5 Ma; Ehlou et al., 2006) and NIST612 as primary standards,

298   and 91500 (Weidenbeck et al., 2004), Aus (Kennedy et al., 2014), and Plešovice (337.13 Ma;

299   Sláma et al., 2008) as secondary standards. Comparison between the mean measured values and

300   the published values for trace elements are reported in Table S1.

301   2.5 MAGEMin thermodynamic calculations

302   The Mineral Assemblage Gibbs Energy Minimization (MAGEMin) thermodynamic

303   package (Riel et al. 2022) was used to calculate stability fields for minerals and their modal

304   proportions using the bulk composition of the dacite sample U1570-26R2-51-54 cm (Fig. 2D, 3)

305   for comparison with the phase assemblage observed in the samples. The MAGEMin program is

306   calibrated with the Holland et al. (2018) thermodynamic dataset and KNCFMASHTOCr

307   calculation system to perform single-point calculations at a given pressure, temperature, and

308   bulk-rock composition to find the most thermodynamically stable phase assemblage.

309   Pseudosections were computed using seven refinement levels and six cores for 0 to 6 kbar (1

310   kbar step size) and for 600 to 1000 °C (100 °C step size). Three pseudosections were calculated

311   to constrain the effect of water, using inputs of 1 wt%, 3 wt%, and 5 wt% H_2O.

312   2.6 Carbon isotopes and mercury concentration in sediments

313   We determined the total organic carbon (TOC) contents and stable carbon isotope ratios

314   ($\delta^{13}C_{org}$) of sediments around the dacitic unit by powdering and decalcifying samples using 1 M

315   HCl for 72 hours. A brief (c. 1 h) heating step at 50 °C during the acidification process was

316   included to remove any siderite that is occasionally present in these sediments. The samples were

317   then rinsed using deionized water, oven-dried at 50°C, and re-homogenized. We performed

318   analyses of a reconnaissance data set using a Thermo Fisher Scientific Flash Elemental Analyzer

319   coupled to a Thermo Fisher Scientific DeltaV Isotope Ratio Mass Spectrometer at the CLIPT

320   Lab, University of Oslo. Based on these initial results, we analyzed an expanded sample set for

321 TOC and $\delta^{13}C_{org}$ using a Thermo Finnigan DeltaPlus XP Mass Spectrometer at the School of

322 Ocean and Earth Science and Technology (SOEST) at the University of Hawaii at Mānoa.

323 We performed mercury analyses at the University of Oxford (UK) using a Lumex

324 915Lab and a Lumex 915+ Portable Mercury Analyzer with a PYRO-915 pyrolyzer attached.

325 Approximately 100 mg of oven-dried (40 ℃) and finely powdered sample was heated to >700

326 ℃ to volatilize the Hg present and Hg concentrations were determined via atomic absorption

327 spectrometry. The instruments were calibrated using the NIST-SRM2587 (paint-contaminated

328 soil) standard (290 ± 9 ppb) and long-term observations of the standards and samples showed

329 that analytical errors for the Hg analyzers were ±6% (Frieling et al., 2023).

330 Total inorganic (TIC) and organic carbon (TOC) concentrations and thermal maturity of

331 organic-carbon on the same sample powders as used for Hg were analyzed at the University of

332 Oxford (UK) with a Vinci RockEval-6 device using standard procedures (Behar et al., 2001). For

333 each sample, ~50 mg of dried powdered material was analyzed, and we assessed reproducibility

334 with an in-house standard of homogenized sediment (~2.8% TOC, ~6% TIC). The standard

335 deviation for TOC, TIC, hydrogen index and Tmax was ±1% of the measured value or better for

336 the in-house standard ($n = 6$). The hydrogen index (HI) and oxygen index (OI) are defined as in

337 Behar et al. (2001) where the mass of released hydrocarbons ("S2") and CO_2 ("S3") in mg is

338 multiplied by 100 and divided by TOC to obtain HI and OI, respectively.

339 **3 Results**

340 3.1 Bulk rock composition

341 Major and trace element bulk rock compositions are reported in Table S2. Compositions

342 obtained on both samples show similar major element compositions (Fig. 3A). The igneous

343 samples from the two boreholes have a SiO_2 content of 66–70 wt%, an alkali (Na_2O+K_2O)

344 content of 6.3 wt%, and an A/CNK (molar $Al_2O_3/(CaO+Na_2O+K_2O)$)) aluminum saturation value

345 of 1.5–1.6, classifying them as peraluminous dacite. Rare earth element (REE) diagrams from

346 both samples (Fig. S2) also show similar enrichment in light-REE (LREE), with La_N/Sm_N ~3.1,

347 and a moderate negative Eu anomaly ($Eu/Eu^* = Eu_N/(Sm_N*Gd_N)\^0.5 ~ 0.65$). The two samples

348 show slightly contrasted heavy-REE (HREE) depletion with a Sm_N/Yb_N ratios of 4.5 and 11.2

349 for the samples from U150D and U1570A, respectively.

350
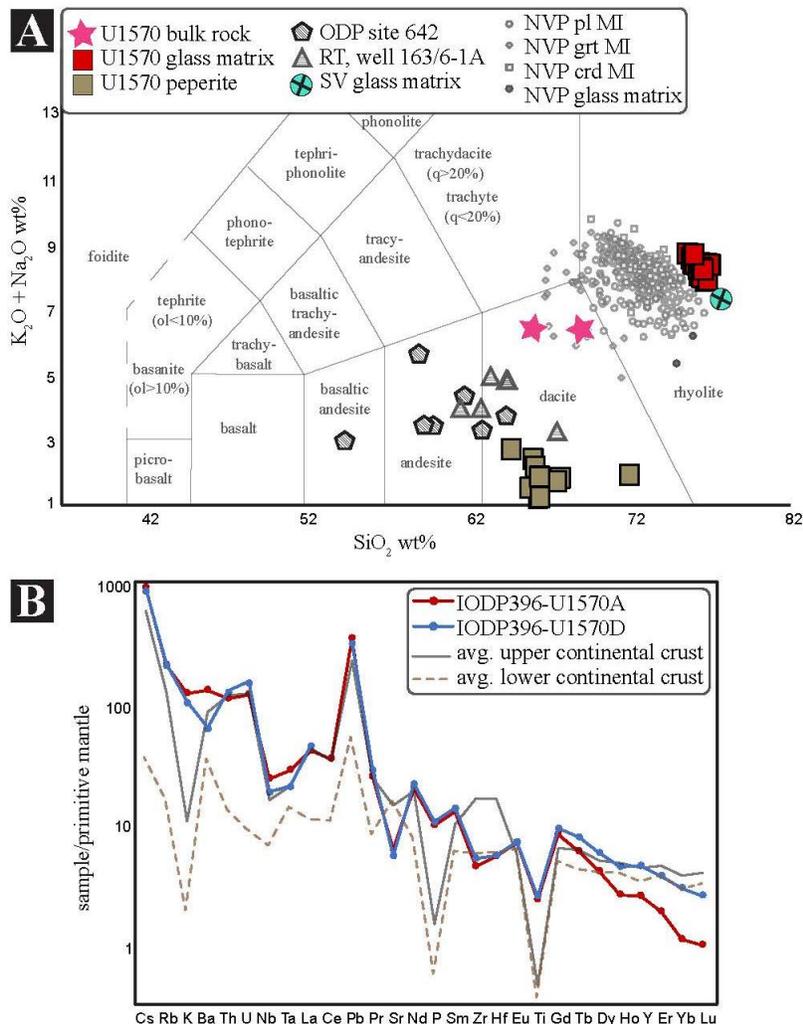

Figure 3. Total alkali-silica (TAS) diagram showing the bulk rock compositions of the U1570

dacite (pink stars); analyses performed on clear glass (red squares) are interpreted as fresh dacitic

melt and analyses performed on the brown glass interpreted as the peperitic matrix (brown

squares). For comparison, hatched pentagon symbols are the bulk rock compositions of the ODP

Leg 104 in Hole 642E dacitic rocks (Eldholm et al., 1989), and hatched triangles represent

dacites from the Rockall Trough (RT) Well 163/6-1 A (Morton et al., 1988). Small open symbols

represent compositions of melt inclusions (MI) in various solid phases (pl=plagioclase; grt =

garnet; crd = cordierite) from the El Hoyazo, Spain enclaves; filled gray circles are the matrix

glass compositions for the El Hoyazo lavas (Álvarez-Valero et al., 2005, 2007). The blue,

crossed circle represents the matrix glass compositions of the Shiveluch Volcano (SV;

Humphreys et al., 2008). (B) Trace element bulk concentrations normalized to the primitive

362   mantle (Sun and McDonough, 1989) of the two dacite samples compare with the average values

363   for the upper and lower continental crust (Rudnick and Gao, 2003).

364   3.2 Petrography and microstructures

365   We estimated phase proportions using the GeoBalance mass balance calculation

366   spreadsheet based on a least squares problem (Li et al., 2020) for inputs of the mean bulk rock

367   composition, and the major element compositions obtained on solid phases and glass. The dacite

368   is composed of 67 ± 12 wt% glass with ~12 wt% cordierite, ~7 wt% plagioclase, ~5 wt% quartz,

369   ~2 wt% garnet, ~1 wt% alkali feldspar, ~1 wt% ilmenite, ~0.5 wt% apatite, and less than 6 wt%

370   of other accessory minerals (e.g., pyrite, zircon) and products of alteration (e.g., kaolinite).

371   The most abundant solid phase, cordierite, occurs as <1 mm to 4 mm large grains. These

372   are subhedral, with distinctive void space around the edges and along cracks (Fig. 4). Subhedral

373   almandine garnets were also identified in most samples. Both garnet and cordierite grains contain

374   abundant solid (ilmenite, pyrite, apatite, zircon) and melt inclusions (Fig. S3). Garnet is also

375   present in inclusion in cordierite (Fig. 5C). Large (2–6 mm) quartz grains are euhedral to

376   subhedral, often with very few or no inclusions (Fig. 4). Garnet, cordierite, and quartz are also

377   often highly fragmented (Figs. 4 and 5). Finally, plagioclase grains are subhedral with few

378   inclusions, sometimes with evidence of dissolution at the margins (Fig. 4A) and alkali feldspars

379   are mostly anhedral and sometimes contain large melt inclusions and embayments (Fig. 4E).

380   Smaller (<1mm) mineral phases disseminated in the samples include ilmenite, pyrite, apatite,

381   kaolinite, and graphite. Graphite is also observed both as a monomineral phase as thin deposits

382   on larger grains (Fig. 5). The matrix is rhyolitic glass (~77 wt% SiO_2; Fig. 3) in ash-sized glass

383   shards and micro-pumices. Mix domains exist where dark sand and silt are mingled within the

384   crystal-rich ash with a preserved grain structure (Figs. 4, 5).
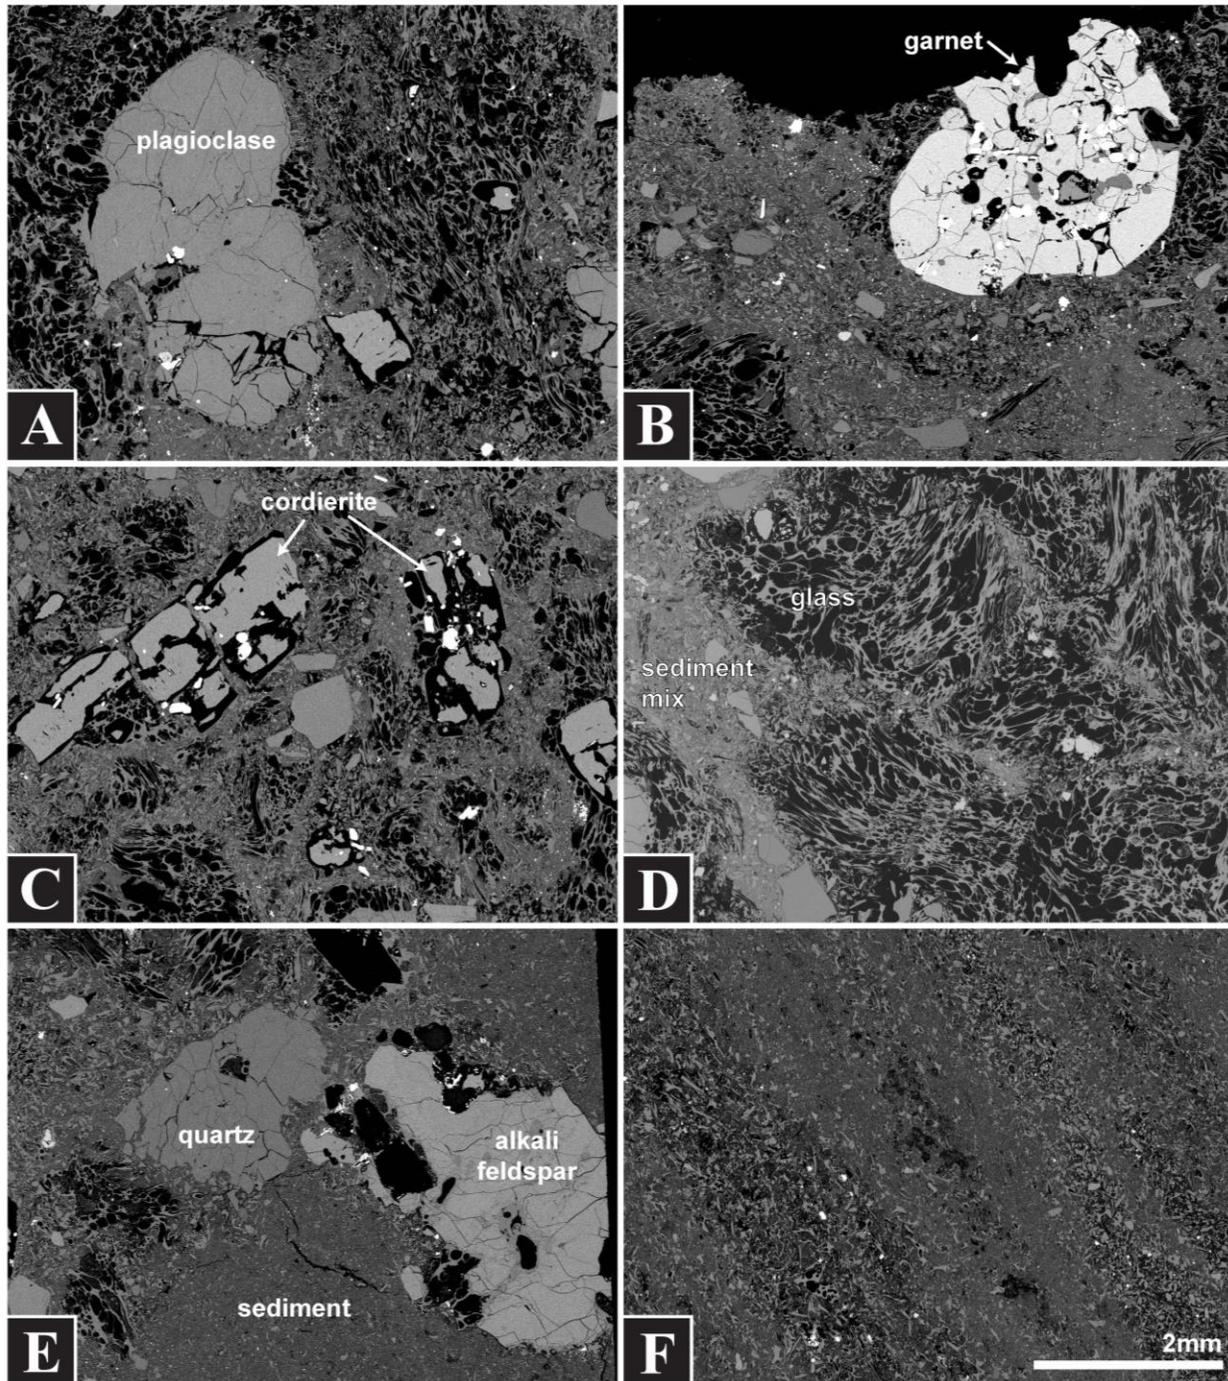

Figure 4. SEM-BSE images highlighting the various textures observed in the dacitic unit. (a)
Plagioclase grain showing dissolution texture on the rim (sample U1570A-26R2-4). (b)
Inclusion-rich garnet grain (sample U1570A-26R2-4). (c) Subhedral fractured cordierite grains
surrounded by void space (sample U1570A-26R2-4). (d) Texture showing mingling between the
vesicular glass and the sediments (sample U1570D-15R1-36). (e) Grains on the basal contact of

391 the dacite with sediments (sample U1570A-27R1-10). (f) Preserved layering of sediments less

392 than a centimeter away from the basal contact of the dacite (sample U1570A-27R1-10). All

393 images have the same scale.
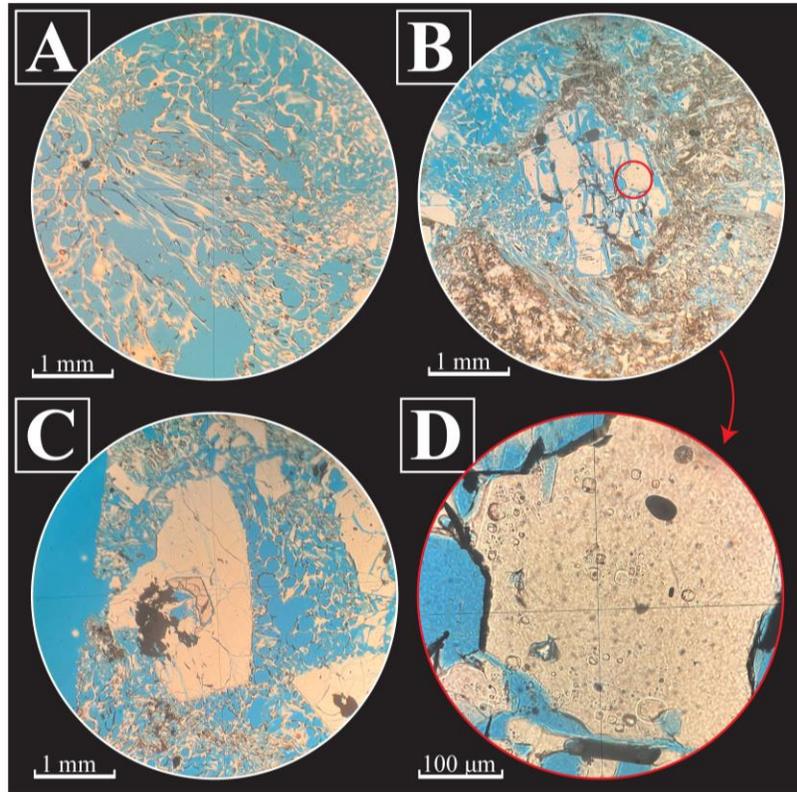

394

395 **Figure 5**. Petrographic images of samples impregnated with blue epoxy to highlight textures and

396 porosity. (a) Example of pumiceous glass texture with elongated and folded vesicles (sample

397 U1570D-14R3-8). (b) Cordierite grain showing fragmented texture with associated graphite

398 (sample U1570A-26R1-26). (c) Garnet and graphite in inclusion in a cordierite grain (sample

399 U1570A-26R2-44). (d) Melt inclusions in cordierite grain from (b).

400 3.3 Mineral chemistry

401 *3.3.1 Major and minor elements*

402 The twelve garnets analyzed are all Fe-rich, almandine-pyrope solid solution (77–85%

403 Alm, 7–15% Py; Fig. 6A; Table 1). They are MnO- and CaO-poor with fractions of spessartine

404 (XSpss) and grossular (XGrs) of 0.040 ±0.003 (1σ) and 0.03 ±0.01 (1σ), respectively (Fig. 6B).

405 The garnets show a relatively constant Mg# (molar Mg/[Mg + Fe]x100) = 12.7% ± 0.7% (1σ).

406   Garnet crystals from samples across boreholes show no significant variations in major element

407   concentrations. Ten of these garnets were large enough to acquire compositional profiles. There

408   is no systematic zonation in the grains, and the compositional variability is limited with 0.05

409   ±0.04 wt% FeO and 0.21 ±0.05 wt% MnO mean relative variability per grain (Fig. S4).

410
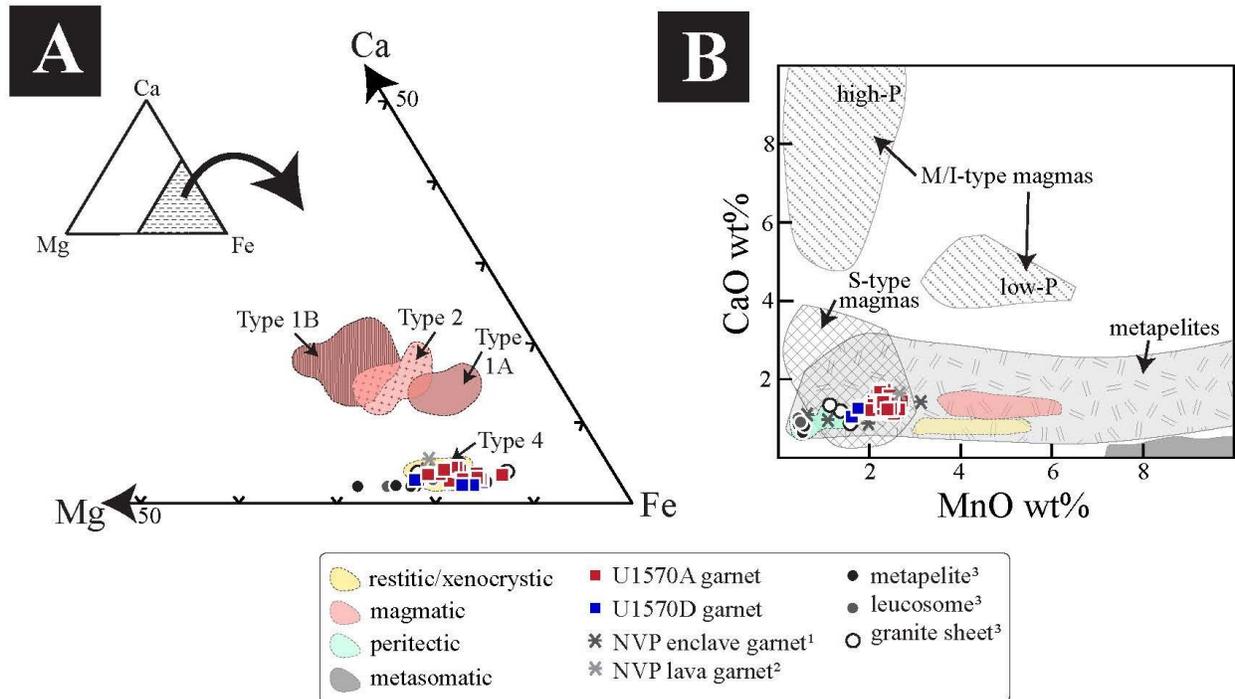

Figure 6. (a) Mg-Ca-Fe ternary plot (Harangi *et al.*, 2001) with the compositions of garnets analyzed in enclaves found in the Neogene Volcanic Province (gray asterisks; Álvarez-Valero & Waters, 2010) and as separated grains in the associated lavas (black asterisks; Hiwatashi et al., 2021) and in Mkhondo Valley Metamorphic Suite rocks separated by the three stages of "selective peritectic phase entrainment": 1) metapelite (black filled circles), 2) leucosome (gray circles), and granite sheet (black open circles; Taylor & Stevens, 2010). (b) CaO vs. MnO wt% plot; colored fields represent different types of garnet adapted from Khedr *et al.* (2022) and gray, patterned fields represent garnets from different sources adapted from Harangi *et al.* (2001). On both plots, restitic and xenocrystic-type garnet compositions are represented by yellow fields and magmatic garnet compositions are represented by light red fields. In (b), peritectic-type garnets are represented by the light blue field and metasomatic garnets by the solid dark gray field. U1570A (red squares) and U1570D (blue squares) garnet compositions are plotted. See text for details.

% Py	11.83	0.69																

425 Oxides concentrations are given as wt. % and elemental concentrations are given as molar fractions. Molar fractions are normalized to 12, 18, 8, and 3 for garnet, cordierite, feldspars,
426 and ilmenite, respectively. Values are the averages of all the measured grains (< >) and the associated standard deviation (1σ). Garnet solid solution end-member proportions are also
427 provided: Alm = almandine, Spss = spessartine, Grs = grossular, Py = Pyrope. Individual analyses are provided in Table S3.

428   The cordierite crystals have an Mg# = 40.8 ±1.6. They have low abundances of Na and K

429   with total alkali (Na + K) molar fraction of 0.02 ±0.03 (Fig. 7). Plagioclase grains classify as

430   labradorite, with 60.2% anorthite and 37.2% albite. Alkali feldspars are 46–72% orthoclase and

431   28–46% albite (Fig. S5A). No significant variability across samples or boreholes is observed. All

432   ilmenite crystals are mostly pure ilmenite with a ≤ 0.01% pyrophanite ($MnTiO_3$) component

433   (Table 1).

434
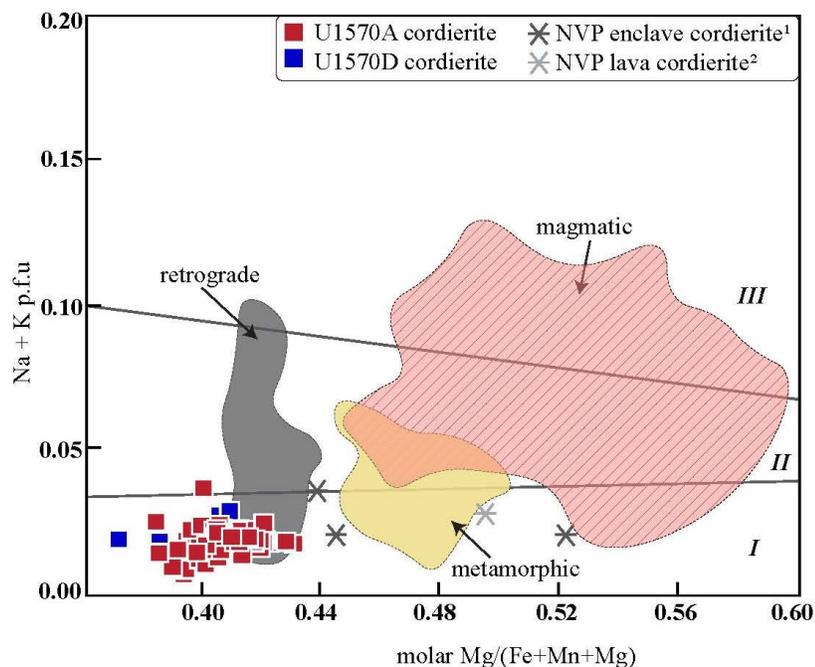

Figure 7. (Na + K) p.f.u (assuming 18 Oxygens) vs. molar Mg/(Fe+Mn+Mg) ratios of cordierite

436   grains from our study: samples from U1570A (red squares) and U1570D (blue

437   squares). Cordierite compositions from enclaves (gray asterisks; Álvarez-Valero & Waters,

438   2010) and separate grains in lavas (black asterisk; Hiwatashi et al., 2021) in the Neogene

439   Volcanic Province volcanic rocks are shown for comparison. Adapted from Pereira and Bea

440   (1994), the magmatic (red), metamorphic (yellow), and retrograde (gray) fields were classified

441   by petrographic textures of cordierite grains. Solid lines define fields based on the chemical

442   compositions of metamorphic (*I*), anatectic (*II*), and magmatic (*III*) cordierite grains.

3.3.2 Trace elements

444   Chondrite-normalized (McDonough & Sun, 1995) garnet REE patterns show notable

445   LREE depletion (Ce_N/Yb_N = 0.0001-0.0009), with strong negative Eu anomalies (Eu/Eu* =

446   0.01–0.04; Fig. 8). HREE slopes are variable, measured by Lu_N/Gd_N ratios ranging from 0.1–

447   20.2 with a difference up to $Lu_N/Gd_N = 16.9$ within a single grain (Fig. S6). While some garnets

448   show core-rim variation with steeper HREE slopes in their cores (Fig. S6), others show more

449   complex patterns. Using the mathematical approach described by Anenburg and Williams

450   (2022), no clear distinction can be made between the garnet grains. Garnet concentrates Sc, Ti,

451   V, and Cr relative to other phases (Table 2). Y concentrations are highly heterogeneous, ranging

452   from 170 to 1323 ppm, with intragranular variability as high as 858 ppm and are generally

453   positively correlated with HREE concentrations.
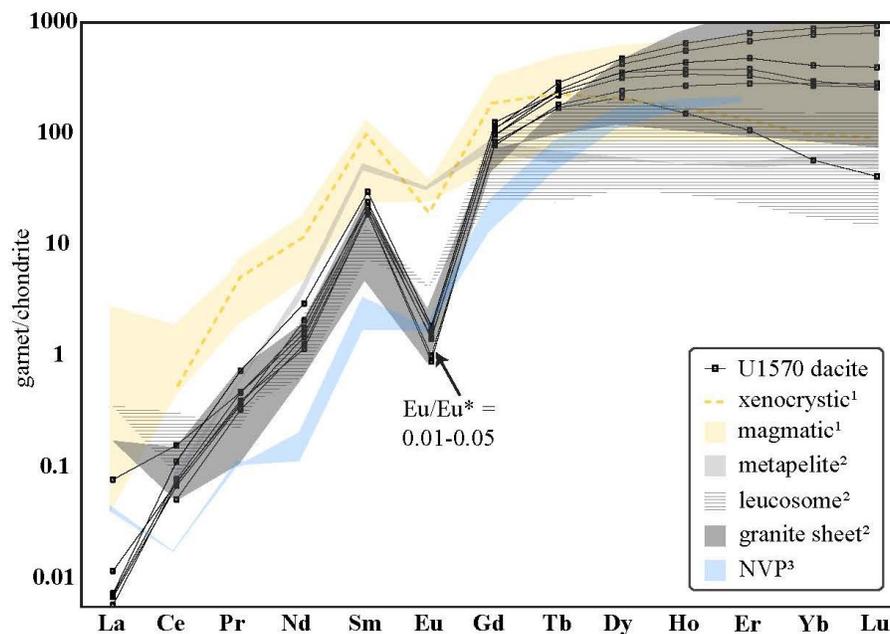

454

455   **Figure 8**. Chondrite-normalized (McDonough & Sun, 1995) garnet REE concentration diagrams.

456   The black lines represent the mean composition of individual garnet grains analyzed in our

457   samples (individual analyses on each garnet are plotted in Fig. S6B), compared with magmatic

458   (yellow field) and xenocrystic (yellow, dashed line) garnets from Northern Pannonian Basin

459   calc-alkaline volcanic rocks. The gray fields represent REE concentrations of garnets from three

460   representative stages of "selective peritectic phase entrainment", (1) the metapelite garnets (light

461   solid gray), (2) leucosome garnets (horizontal gray lines), and (3) granite sheet garnets (solid

462   dark gray. Neogene Volcanic Province volcanic rock garnets are represented by the blue field.

463   Subscripts 1, 2, and 3 in the legend correspond to Harangi et al. (2001), Taylor & Stevens

464   (2010), and Álvarez-Valero & Waters (2010), respectively.

465 **Table 2.** Mean trace element concentrations (µg/kg) for major solid phases in the dacite.

466 Values are the averages of all the measured grains (< >) and the associated standard deviation (1σ). Individual analyses are
467 reported in Table S4.

468   Trace element analysis for cordierite crystals shows they are very REE-depleted (ΣREE_N

469 < 1.5 ppm). Cordierites are Zn-enriched and Sr-depleted relative to other phases (Zn = 277 ± 18

470 ppm, Sr = 0.07 ± 0.13 ppm; Table 2). Plagioclase is LREE-enriched relative to HREE (La_N/Sm_N

471 = 5.6–12.0). They are relatively enriched in Sr, Ti, and Cr with small positive Eu anomalies

472 (Eu/Eu* = 5.0–10.0; Fig. S5B; Table 2). In comparison, alkali feldspars are significantly more

473 LREE-depleted, but present more fractionated patterns (La_N/Sm_N = 10.1–125.0). They also

474   concentrate more Ti and less Sr than plagioclase and have strong positive Eu anomalies (Eu/Eu*

475   189.2–521.0; Fig. S5B; Table 2).

476

477   3.4 U-Pb zircon ages

478   Zircon grains have only been observed as inclusions in garnet and cordierite and are

479   dominantly subhedral with rare euhedral crystals. Many of the zircons are fractured and range

480   from 10 to 100μm in diameter (Fig. 9A). Zircon analyses were plotted on a Tera-Wasserburg

481   concordia plot (^{238}U/^{206}Pb vs. ^{207}Pb/^{206}Pb; Tera & Wasserburg, 1972) in the IsoplotR toolbox

482   (Vermeesch, 2018). The data define a ternary mixing field in Tera-Wasserburg space with the

483   endmembers interpreted as (1) dominant younger populations, with a subset of concordant

484   analyses and (2) sparse older inherited population of zircon. Non-anchored, uncertainty-weighted

485   linear regression (i.e. model-1 fit) of the young, concordant analyses with the array of young

486   analyses containing variable amounts of common Pb (population 1, Fig. 9B) yielded an initial

487   lead composition of 0.79 ± 0.1 (^{207}Pb/^{206}Pb) and lower intercept of 54.8 ± 1.1 Ma (MSWD =

488   1.7). The lower intercept of a linear regression anchored to Stacey-Kramer initial Pb value of

489   0.85 also yielded a 54.8 ± 1.1 Ma (mean square weighted deviation, MSWD = 1.7; Ludwig,

490   1997; Andersen, 2002; Chew et al., 2014). Spot dates were calculated using the Stacey-Kramer

491   anchored ^{207}Pb correction (Fig. 9A). Analyses with ^{238}U/^{206}Pb less than 105 and concordance

492   outside of 0.9–1.05 were excluded from the weighted mean calculation. The weighted mean date

493   of 54.6 ± 1.1 Ma, calculated using concordant analyses from population 1, is interpreted as the

494   magmatic age of the dacite. The analyses interpreted as inherited (#2 above) yielded spot dates

495   ranging from 61–2500 Ma (Fig. S7).

496
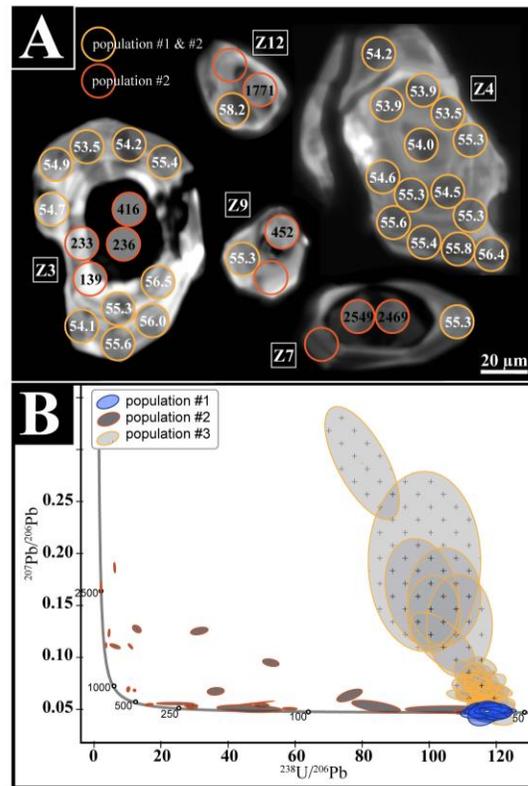

Figure 9. (a) Representative cathodoluminescence images of zircon grains from sample U1570A-26R-2-4. Circles represent LA-ICP-MS analysis locations, and the numbers are the calculated spot age for that analysis. Empty circles show spot ages that did not fall on the regression from the weighted average and were too discordant (concordance >0.9) to calculate ages. Populations #1 and #3 (magmatic) and #2 (inherited) are represented in yellow and orange, respectively. (b) U-Pb isotope results for zircon on Tera-Wasserburg Concordia plot. Only analyses in blue were used to calculate the formation age of the dacite (see text for details). Population #1 includes samples that fit a regression from the weighted average to the expected original $^{207}Pb/^{206}Pb$ and represent magmatic young zircons. Samples that do not fit the regression are included in population #2, representing older inherited zircon.

3.5 Sedimentary mercury concentration and organic carbon maturation data

The stable carbon isotope analyses of bulk organic matter ($\delta^{13}C_{org}$), total organic carbon (TOC) and mercury (Hg) contents in the sediments collected in borehole U1570A and U1570D

511   are plotted in Figure 2 and reported in Tables S5 and S6. Sedimentary mercury concentrations

512   are ~190 ppb (mean) for the sediments analyzed for U1570D (81.23 meters below surface, mbsf,

513   CSF-A to 192.28 mbsf). Two strongly Hg enriched samples (> 1 ppm; 87.25 and 172.4 mbsf)

514   were found but these occur 10s of meters from the dacitic unit. For other samples, mercury

515   concentrations are above average shale values (~ 62 ppb, Grasby et al., 2019) throughout the

516   succession but no clear trends in Hg concentration were observed towards the dacite unit.

517   Organic-carbon maturation data obtained through RockEval analyses indicates the

518   organic-matter preserved in the sediments is immature; Tmax averages ~ 405 ºC. RockEval

519   parameters HI (mean ~50) and OI (mean ~130) signal a dominant terrestrial organic-matter

520   composition. Total organic carbon concentration measurements yielded ~0.6 wt% for the

521   Paleocene interval and ~1.1 wt% for the lower Eocene and, similar to Hg concentrations, none of

522   the RockEval parameters (TOC, HI, OI, Tmax) show trends towards the dacite unit.

523

524   **4 Interpretation of texture and mineral chemistry of garnet and cordierite**

525   Our samples contain mineral phases commonly found in crustal metapelites and restites,

526   particularly garnet and cordierite produced during crustal anatexis (Fig. 4, 5; Harley &

527   Carrington, 2001; Vry et al., 1990; White & Chappell, 1977; Stevens et al., 1995, 2007;

528   Weinburg & Hassalova, 2015). In this context, these minerals could be (1) liquidus phases

529   produced during the crystallization of a magma as phenocrysts; (2) disseminated xenocrysts from

530   the original protolith; or (3) peritectic phases entrained during magma transport. A magmatic

531   chemical signature would indicate they are liquidus phases, while a metamorphic signature

532   would indicate they are either disseminated xenocrysts or peritectic phases which preserve the

533   chemistry of the protolith. Below, we use several proxies to distinguish magmatic and

534   metamorphic major and trace element compositions of garnet and cordierite.

535   Harangi et al. 2001 and Bach et al. (2012) presented similar classifications based on the

536   Ca, Mg, and Fe (±Mn) components of the garnet solid solution. Both studies show that magmatic

537   garnets are systematically more enriched in grossular than metamorphic garnets (Fig. 6). Garnet

538   compositions in our study are relatively depleted in grossular, overlapping the compositions of

539   xenocrystic garnets described in Harangi et al. (2001) and plotting near metamorphic garnet

540   compositions in Bach et al. (2012)'s classification, but with a more significant almandine-

541   spessartine enrichment in comparison to the garnet compositions reported in their study.

542   According to the classification defined by Pereira and Bea (1994) based on alkali content and

543   Mg# (= molar Mg / [Mg+Fe+Mn]), the cordierite grains in our samples also show a metamorphic

544   major element signature (Fig. 7).

545   Harangi et al. (2001) did not report trace element analyses on pure xenocrystic garnets

546   but rather on composite garnets, interpreted as xenocryst cores surrounded by magmatic rims

547   (Fig. 8). Both the magmatic and composite garnets from their study show REE patterns similar to

548   those observed in our samples, displaying substantial LREE depletion and variable HREE slope.

549   While none of them have negative Eu anomalies as prominent as those observed in the garnet

550   grains from the Site U1570 dacite, the Eu anomalies for the xenocrystic cores of composite

551   garnets (Eu/Eu* = 0.14) are stronger than those reported for the magmatic garnets (Eu/Eu* =

552   0.17–0.68; Fig. 8). Harangi et al. (2001) also reported depleted Y (277 ppm) and enriched Zr and

553   Hf (178 and 2.75 ppm, respectively) for the xenocrystic core compositions relative to magmatic

554   compositions. In comparison, garnets from our study have more variable Y contents (170–1323

555   ppm) and lower Zr and Hf concentrations (9–47 and 0.20–0.84 ppm, respectively; Table 2).

556   However, trace elements concentrations of magmatic garnets reported in Bach et al. (2012) show

557   Y, Zr, and Hf variability covering the entire range of those presented for magmatic and

558   xenocrystic garnets in Harangi et al. (2001), indicating that these elements are not reliable

559   proxies for garnet origin.

560   In their study of mid-crustal anatectites from the Mkhondo Valley Metamorphic Suite,

561   Swaziland, Taylor and Stevens (2010) outlined how garnet can undergo several stages of

562   entrainment that result in modifications to both their major and trace element compositions (Fig.

563   10). By analyzing almandine garnet from metapelites, leucosomes, and granite sheets, they

564   proposed these garnets represent a sequence of processes related to "selective peritectic phase

565   entrainment," in which only solid peritectic products become entrained by associated melts

566   (Stevens et al., 2007). This model provides a mechanism to produce hot, water-undersaturated,

567   granitic magmas. Preferential entrainment of garnet and ilmenite during high-temperature,

568   incongruent, fluid-absent melting of biotite metapelites results in an increase in A/CNK, Mg#,

569   and Ca content and a decrease in Si and K in the magma.

570
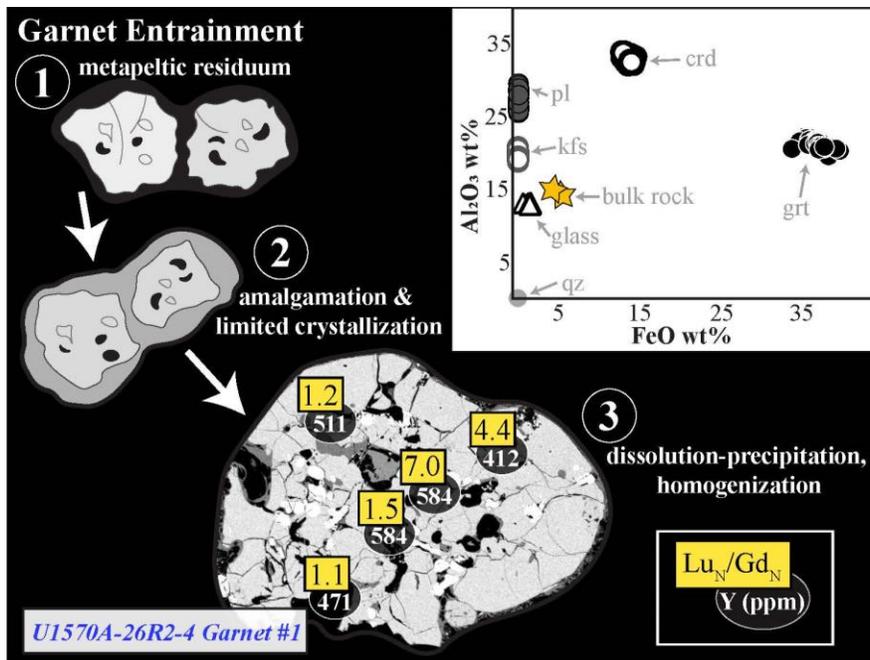

Figure 10. Summary of thermobarometric calculations. The gray dashed line represents the mean temperature calculated for Ti concentration in quartz using Wark and Watson (2006)'s original TitaniQ thermometer with no pressure correction (standard deviation represented by the gray field). Black circles represent the pressure-dependent thermometer for Ti concentration in quartz for Huang and Audétat (2012). For comparison the pressure correction from Thomas et al. (2010) is also plotted (gray circles). The vertical red line and red field represent the mean temperature and standard deviation calculated using the Fe-Mn exchange between garnet-ilmenite (Grt-Ilm; Pownceby et al., 1991). The red triangles show the pressures calculated with the garnet barometer (Wu, 2019) and the blue squares represent the temperatures calculated with the garnet-cordierite (Grt-Crd) thermometer (Kaneko & Miyano, 2004). The pressure and temperature field obtained using 1wt% H_2O and the bulk rock composition in the MAGEMin package (Riel et al., 2022) for the assemblage observed in our samples is shown by the hatched triangular area. Subscripts in legend represent references: (1) Wark and Watson (2006), (2) Thomas et al. (2010), (3) Huang and Audétat (2012), (4) Pownceby et al. (1991), (5) Kaneko & Miyano (2004), (6) Wu (2019), (7) Riel et al. (2022).

From their study, Taylor and Stevens (2010) describe three stages of the "selective peritectic phase entrainment model. Peritectic garnet growth in rapid partial melts of metapelites represents the first stage of entrainment and these garnets have Mg# = 20–27, XSpss = 0.01, and

589   homogenous compositions. The second stage of entrainment is present in the peritectic garnets

590   from leucosomes, interpreted to have undergone limited recrystallization and some

591   amalgamation at high temperatures with Mg# = 20–22 and XSpss = 0.01. Finally, the garnets

592   from the granite sheets are rounded and euhedral, resulting from dissolution-precipitation

593   reactions, amalgamation, and re-equilibration with the magma. This third stage is further divided

594   into large (0.8–4 mm) garnets with Mg# = 18–21 and XSpss = 0.02 and very small (75–600 μm)

595   garnets with Mg# = 12–14 and XSpss = 0.02–0.03. Both large and small garnets from granite

596   sheets have rims with slightly lower Mg# and higher XSpss contents than their cores (Taylor &

597   Stevens, 2010). With homogenous Mg# = 12–13 and XSpss = 0.04, the garnets in our samples

598   are compositionally most similar to those from the granite sheet (Fig. 6). Additionally, the

599   presence of melt inclusions in both garnet and cordierite (Fig. 5) provides evidence for rapid

600   crystal growth (Cesare et al., 2011).

601   Taylor and Stevens (2010) also presented chondrite normalized REE data for the garnets

602   in their study. Representing the first stage of garnet entrainment, metapelite garnets have flat,

603   relatively depleted HREE patterns and weak negative Eu anomalies (Lu_N/Gd_N = 0.98–0.16,

604   Eu/Eu* = 0.5). Leucosome garnets from the second stage have slightly steeper HREE slopes and

605   much stronger negative Eu anomalies (Lu_N/Gd_N = 1.59–0.56, Eu/Eu* = 0.07). Garnets from the

606   third stage, the granite sheets, have the steepest HREE slopes and the most pronounced negative

607   Eu anomalies (Lu_N/Gd_N = 1.15–28.38, Eu/Eu* = 0.03). The strongly negative Eu anomalies of

608   the U1570 dacite garnets overlap with the latter stages of entrainment, where evidence of

609   dissolution-precipitation reactions is prominent. Taylor and Stevens (2010) also reported changes

610   in HREE slope from steeper in the core to flatter in the rim of garnet in the granite sheets, and

611   complex zonation of yttrium (Y) concentrations, which they attribute to the amalgamation of

612   grains. The HREE slopes in the Site U1570 dacite garnets cover the range presented in Taylor

613   and Stevens (2010), though most overlap with the stage three granite sheet garnets, and some

614   show evidence of the same zonation patterns from core to rim (Fig. 10). The garnets from our

615   study also have similarly complex Y zoning, with a broad pattern of Y enrichment in the cores

616   relative to the rims (Fig. 10). Finally, the bulk composition of our samples shows depletion

617   in HREE, Zr and Hf (Fig 3B, S2) consistent with the presence of residual garnet in the source.

618   Peritectic garnets are expected to be enriched in HREE (Fig. 8; Taylor and Stevens, 2010). While

619   present as large grains, the fraction of garnet in our samples is relatively small (< 2 wt.%).

620   Hence, if some of these newly formed grains were not entrained in the magma, they might

621   explain the HREE (and Hf and Zr) depletion of the bulk rock.

622   In summary, garnet compositions in our samples have notable similarities in major and

623   trace element compositions with peritectic phases entrained in a melt. Notably, they are

624   chemically similar to entrained garnets resulting from dissolution-precipitation reactions grains

625   in a magma. Through re-equilibration with the magma and amalgamation of new grains formed

626   by peritectic reaction, dissolved metapelitic garnets can be re-precipitated with their major

627   elements homogenized (Taylor & Stevens, 2010). These processes can produce garnets with

628   magmatic textures, xenocrystic, homogenous, major element chemistry, and complex trace

629   element zonation through peritectic growth in a hot, water-undersaturated magma during

630   metapelitic melting (Clarke, 2007). At Mimir High, the main solid peritectic products which are

631   transported within the dacite magma toward the surface are Fe-rich garnet and cordierite,

632   resulting in a bulk rock composition with high A/CNK and Fe contents and relatively low Si and

633   K contents (Figs. 3, 10).

5 Geothermobarometry and pseudsections

635   The mineral textures (subhedral morphology, melt inclusions) and mineral chemistry of

636   the garnet and cordierite grains support their origin as products of peritectic melt reactions that

637   have been entrained in the dacitic melt. During evolution and transport the dacite may have been

638   impacted by variable degrees of re-crystallization and chemical re-equilibrium. As such, the

639   observed mineral assemblage and bulk rock chemistry can be used to constrain the pressure,

640   temperature, and water saturation conditions of melt generation of the magma.

641   5.1 Ti in quartz, TitaniQ thermometer

642   Wark and Watson (2006) formulated the TitaniQ thermometer based on the temperature-

643   dependent substitution of titanium for silicon in the quartz matrix over a temperature range of

644   600–1000 °C at 10 kbar. Their equation for rutile-undersaturated rocks is:

645    $$T(°C) = \frac{-3765}{\log\left(\frac{x_{Ti}^{qtz}}{a_{TiO_2}}\right) - 5.69} - 273 \qquad (1)$$

646   where X_{Ti}^{qtz} is the concentration (ppm) of Ti in quartz and a_{TiO_2} is the activity of TiO₂ in the

647   melt.

648   For silicic igneous rocks that are TiO₂ undersaturated, indicated by the lack of rutile as a

649   stable phase, the activity of titanium in the melt < 1 and must be estimated to apply TitaniQ.

650   Ghiorso and Gualda (2013) calculated the activity of titania in the liquid relative to rutile

651   saturation (aTiO₂) for the Shiveluch Volcano dacite using two independent methods: one based

652   on the composition of coexisting spinel and ilmenite in the magma, and one calculated with

653   rhyolite-MELTS (Gualda et al., 2012) using the rhyolitic matrix glass composition from

654   Humphreys et al. (2008). This melt composition is comparable to the rhyolite glass in our sample

655   with 78.0 wt% SiO₂, 7.4 wt% alkali content, 12.4 wt% Al₂O₃, and 0.3 wt% TiO₂ (Fig. 3). The

656   two sets of calculations intersect for aTiO₂ between 0.75 and 0.90 for 730–800 °C (see Fig. 3 in

657   Ghiorso & Gualda, 2013).

658   Using equation (1), variation of aTiO₂ within ± 0.1 only results in temperature variation

659   within ± 20°C. The mean Ti concentration and its one standard deviation in quartz hosted by the

660   dacite is 142.04 ± 37.8 ppm. Assuming aTiO₂ = 0.8, we obtain a mean crystallization temperature

661   of 817 ± 42 °C (Fig. 11; Table 3).

662   A few studies have reformulated TitaniQ to include the effect of pressure (e.g., Thomas

663   et al., 2010; Huang & Audétat, 2012). In their experimental study, Thomas et al. (2010) showed

664   that the solubility of Ti in quartz decreases with increasing pressure. They present a pressure-

665   dependent TitaniQ thermometer calibrated between 5 and 20 kbar. Huang and Audétat (2012),

666   however, argued that Thomas et al. (2010)'s thermometer overestimates Ti solubility, and

667   consequently the effect of pressure, in their experiments. Using new rutile-saturated experiments

668   performed between 1 and 10 kbars, the authors proposed the following equation:

669    $$logTi = -0.27943 \left(\frac{10^4}{T}\right) - 660.53 \left(\frac{P^{0.35}}{T}\right) + 5.6459 \qquad (2)$$

670   where Ti is the rutile-saturated concentration of Ti (in ppm) in quartz, T the temperature in

671   Kelvin, and P pressure in kbar. For natural samples that are not saturated in rutile, $X_{Ti}^{qtz-sat}$ must

672   be calculated using aTiO₂, such as $X_{Ti}^{qtz-sat} = X_{Ti}^{qtz}/a_{TiO_2}$. Temperatures calculated in our

673   study using the Huang and Audétat (2012) thermometer and $a_{TiO_2} = 0.8$ range from 886 ±45 °C

674   at 5 kbar down to 740 ±39 °C at 1 kbar (Fig. 11; Table 3).
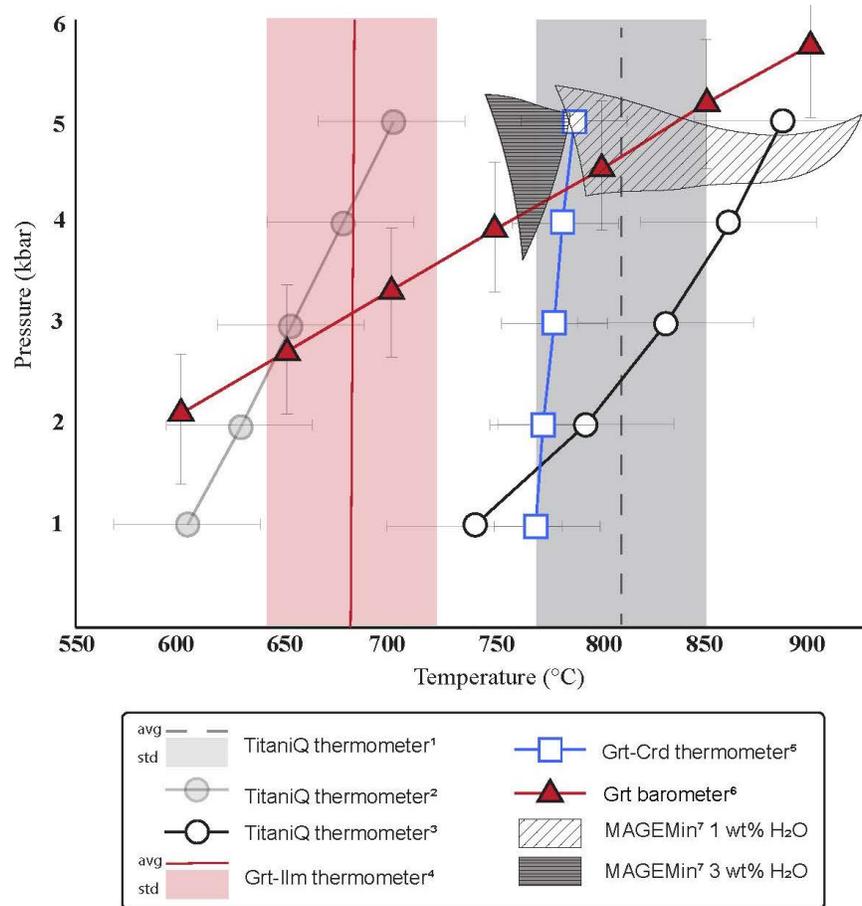

Figure 11. Schematic diagram for selective peritectic phase entrainment model for garnet grains. (1) Grains of peritectic phases from metapelitic residuum become entrained in the melt. (2) Residual grains experience limited new crystallization and amalgamate in the second stage. (3) BSE image of garnet from sample U1570A-26R2-4 representing the third stage in which amalgamated grains dissolve and re-precipitate as single grains with homogenized major element compositions but variable trace element compositions. Adapted from Taylor and Stevens (2010). LA-ICP-Ms analysis locations are represented by yellow squares; values on yellow squares are the corresponding HREE slopes (i.e., Lu_N/Gd_N, chondrite-normalized ratio). Values in black circles are the Y (ppm) concentrations at the same location. The Al_2O_3 vs. FeO wt% plot shows bulk rock compositions (yellow stars) compared to major phases including garnet (black filled

686 circles), cordierite (black open circles), plagioclase (dark gray filled circles), alkali feldspar (gray

687 open circles), quartz (light gray filled circles), and matrix glass (black open triangles).

690 Pseudosection results are given as ranges for which the observed phase assemblage is stable. Thermometer
691 results are given as an average and one standard deviation or temperature with corresponding input pressures
692 if applicable. Barometers results are given as an average and one standard deviation for each input
693 temperature.

694   5.2 Garnet-ilmenite and garnet-cordierite thermometers

695   Xenocrysts present in the dacite allow for the use of the garnet-ilmenite geothermometer

696 based on Fe-Mn exchange reactions and the garnet-cordierite geothermometer based on Fe-Mg

697 exchange reactions.

698   The Fe-Mn exchange between garnet and ilmenite was investigated by Pownceby et al.

699 (1987), who developed a pressure independent geothermometer. Pownceby et al. (1991)

700 reinvestigated the original thermometer to include the influence of grossular content in garnet

701 and presented the thermometer:

702
$$T = \frac{14918 - 2200(2X_{Mn}^{Ilm} - 1) + 620(X_{Mn}^{Grt} - X_{Fe}^{Grt}) - 972X_{Ca}^{Grt}}{R \ln K_d + 4.38} - 273.15 \qquad (3)$$

703   where R is the gas constant, T is the temperature in Celsius, X_{Mn}^{Ilm} is the molar concentration of

704   Mn in ilmenite, and X_{Mn}^{Grt}, X_{Fe}^{Grt}, X_{Ca}^{Grt} are the molar concentrations of Mn, Fe, and Ca in garnet,

705   respectively. K_d is the distribution coefficient defined by:

706
$$K_d = \frac{(X_{Mn}^{Grt}) \times (X_{Fe}^{Ilm})}{(X_{Fe}^{Grt}) \times (X_{Mn}^{Ilm})} \qquad (4)$$

707   Using experimental results performed at 600–1000 °C and 10 kbar and $FeTiO_3$-$MnTiO_3$

708   activity data, their thermometer has a resolution of $\pm$ 30–50°C. In our study we only used this

709   thermometer on ilmenite inclusions in garnet to account for the rapid diffusion of Fe-Mn in

710   ilmenite. In fact, the relatively slow Fe-Mn diffusion in garnet effectively shields the ilmenite

711   from re-equilibration and records temperatures for garnet growth (Pownceby et al., 1991).

712   Garnet-ilmenite temperature results for seven garnets in the dacite give an mean of 686 ± 37 °C

713   (Fig. 11; Table 3).

714   The garnet-cordierite geothermometer is commonly used to determine temperatures in

715   high-grade amphibole and granulite facies metamorphic rocks (Spear & Selverstone, 1983).

716   However, it is considered to be a poorly calibrated thermometer because cordierite is prone to

717   severe alteration in high-grade metapelites. We note, however, alteration is not observed in our

718   sample (Figs. 4, 5). In addition, the presence of a garnet inclusion in cordierite (Fig. 5C) supports

719   chemical equilibrium between the two phases. Several calibrations have been proposed for this

720   thermometer (e.g., Thompson, 1976; Holdaway & Lee, 1977; Perchuck et al., 1985; Wells,

721   1979). Here we present results obtained with Kaneko and Miyano (2004)'s calibration:

722
$$T = \frac{-26144.7 + (-0.122 + W_V^{Grt})(P-1) + W_H^{Grt} - 80.44(Mg^{Crd} - Fe^{Crd})}{-12.7094 - R \ln K_d + W_S^{Grt} + 1.642(Mg^{Crd} - Fe^{Crd})} - 273.15 \qquad (5)$$

723   where T is Celsius, and P is in bar. The W_H^{Grt}, W_S^{Grt}, and W_V^{Grt} are the non-ideal mixing terms for

724   the garnet solid solution based on Berman (1990)'s expression (see equations A5, A6, and A7,

725   respectively in Kaneko and Miyano, 2004). The terms Fe^{grt}, Mg^{cd}, etc. denote the molar fractions

726   of Fe and Mg in the garnet and cordierite solid solutions such as $Mg^{Crd} = Mg/[Mg + Fe]$, and

727    $Mg^{Grt} = Mg/[Mg + Fe + Ca + Mn]$, with Mg, Fe, Ca and Mn in mol. %. Finally, the exchange

728   coefficient (K_d) defined by:

729     $$K_d = (Fe^{Grt})/(Mg^{Grt}) \times (Mg^{Crd})/(Fe^{Crd}) \qquad (6)$$

730   The estimated absolute error for Kaneko and Miyano (2004)'s calibration is ± 45°C.

731   Calculated temperatures using the compositions of garnet and cordierite grains in our samples

732   and equation (5) and (6) show significantly higher temperatures (~770-790 °C, Fig. 11; Table 3)

733   than the garnet-ilmenite thermometer, with an effect of pressure smaller than the estimated

734   uncertainty on the temperature.

735   ### 5.3 Garnet barometer

736   While commonly used to determine pressures for metapelites, the garnet-Al_2SiO_5-

737   plagiocalse-quartz (GASP) barometer (Holdaway, 2001) cannot be applied to our samples due to

738   the absence of an aluminosilicate and biotite in the assemblage. Additionally, the garnet-rutile-

739   ilmenite-plagioclase-silica (GRIPS) barometer (Bohlen & Liotta, 1986) is not recommended for

740   pressures below 6 kbar (Wu & Zhao, 2006). Instead, we use the garnet barometer developed by

741   Wu (2019) for metapelitic assemblages to estimate the pressure recorded by the phase

742   assemblage in our samples. In fact, Wu (2019)'s barometer was initially developed because

743   plagioclase is often CaO-poor or absent in metapelites, making barometers such as GASP and

744   GRIPS less precise or unusable. It is empirically calibrated using natural metapelite samples with

745   pressure and temperature conditions of 1–15 kbar and 430–900 °C for garnets with molar

746   fractions of calcium and iron in the solid solution of 0.02–0.29 and 0.42–0.91, respectively:

747     $$P\ (bar) = \frac{-8904.5 + 24.542T + 0.45RT\ \ln(Ca^{Grt}/Fe^{Grt}) + 0.15aT + 0.15c}{1 - 0.15b} \qquad (7)$$

748   T is in Kelvin and a, b, and c are polynomial coefficients (see equations (5), (6), and (7),

749   respectively in Wu (2019), which account for differences of excess chemical potential between

750   grossular and almandine components in the garnet solid solution; Holdaway, 2001). The

751   estimated error for pressures calculated using equation (7) is less than ±1.3 kbar. Using our

752   sample's mean garnet composition (Table 2), we obtain a range of pressures from ~2.1 kbar at

753   600 °C to ~5.7 kbar at 900 °C (Fig. 11; Table 3).

754   ### 5.4 Pseudosections

755   The phase assemblage calculated with MAGEMin (Riel et al., 2022) that includes garnet

756   (grt), cordierite (crd), ilmenite (ilm), two feldspars (fsp^2), quartz, (qz), spinel (spl), and silicate

757   melt (m) best matches the assemblage observed in the Site U1570 dacite. The pseudosection

758   calculated with 1 wt% H_2O shows this assemblage being stable at 775–915 °C for pressures

759   between 4.3–5.3 kbar (Fig. 12; Table 3). With 3 wt% H_2O, the range of temperatures over which

760   the phase assemblage observed in our samples is stable is much narrower (750 °C and 790 °C)

761   but the pressure range is expanded (3.7–5.2 kbar; Fig. S8; Table 3).
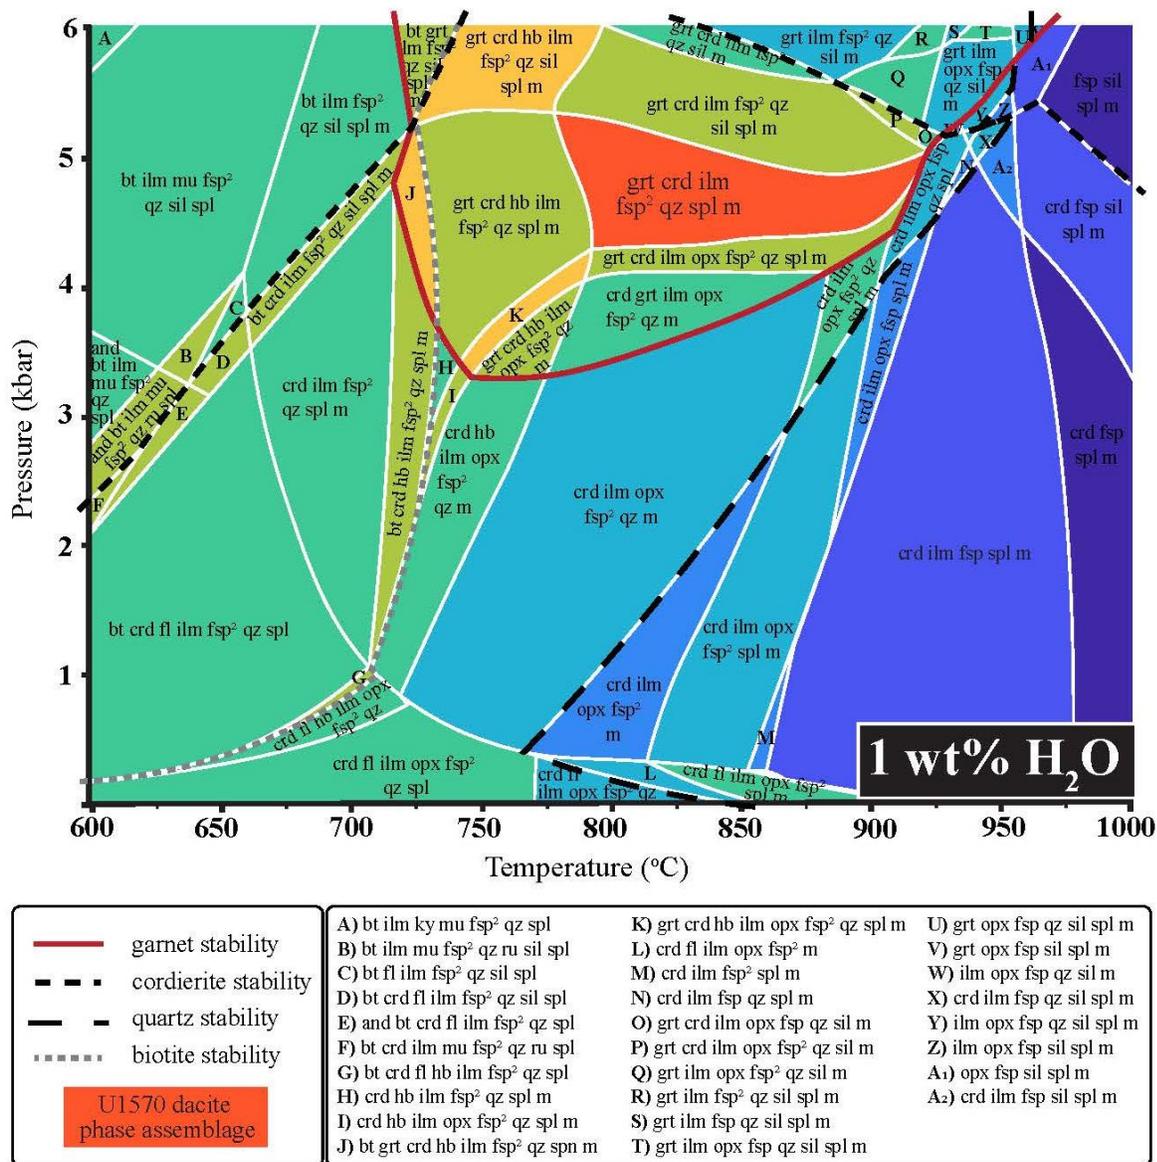

762

763   **Figure 12**. Pseudosection calculated from the bulk rock composition acquired on the sample

764   U1570-26R2-51-54 (Fig. 2D), assuming 1 wt % H_2O contents, using the MAGEMin

765   thermodynamic package (Riel et al., 2022). Colored fields ranging from blue to yellow represent

766   an increasing number of phases in an assemblage; the dark orange field represents the one that

767   reproduces the phase assemblage observed in the U1570 dacite (grt-crd-ilm-fsp^2-qz-spl-m).

768   Garnet stability field is represented by the solid red line, cordierite stability field with a black,

769   short-dashed line, quartz stability field with a black, long-dashed line, and biotite stability field

770   with a gray, dashed line. Phases include: andalusite (and), biotite (bt), cordierite (crd), ternary

771   feldspar (fsp, fsp^2 indicates two compositions of ternary feldspar), garnet (grt), hornblende (hbl),

772   ilmenite (ilm), muscovite (ms), olivine (ol), quartz (qz), sillimanite (sil), spinel (spl, spl^2

773   indicates two compositions of spinel), silicate melt (m), and aqueous fluid (H_2O). Calculations

774   with 3 and 5wt% H2O in the bulk compositions are shown in Fig. S8.

775   Finally, this phase assemblage is not reproduced in the pseudosection calculated with 5 wt%

776   H_2O. The pressure and temperature range where garnet, cordierite, and quartz overlap (~3.3 kbar,

777   ~675–700 °C) also includes amphibole in the assemblage and lacks the two feldspars (Fig. S8;

778   Table 3). In the following, we therefore assume that the bulk water content of the Site U1570

779   dacite is low (< 3 wt% H_2O).

780   **6 Discussion**

781   6.1 Dacite origin and emplacement

782   To understand the potential implications that dacite from Site U1570 may have for large

783   igneous province emplacement, continental breakup, and thermogenic gas production, it is

784   necessary to consider its petrogenesis. Below we discuss (1) the emplacement of the dacite using

785   textural observations and stratigraphic constraints and (2) the origin of the dacite with results

786   from thermodynamic calculations, thermobarometry, and phase composition analyses.

787   *6.1.1 Stratigraphic constraints*

788   The highly vesicular nature of the unit is consistent with emplacement of the dacite in a

789   shallow environment at low pressure (Fig. 4, 5). For evolved melts, highly vesicular pyroclasts

790   (>80% vesicularity) only form above water depths of 500 m, unless the dissolved magmatic

791   water content is unrealistically high (>7 wt%; Wright et al., 2003). Dacitic melts containing a

792   few wt% water may be expected to have viscosities of 10^7 to 10^6 Pa.s for pure melt between 750

793   and 850 °C (Giordano et al., 2008). Such melts would be prone to explosive fragmentation

794   during transport to the surface, with exsolution of the volatiles and formation of vesicles

795   resulting in increasing bulk viscosity and further promoting fragmentation. Such rapid

796   decompression and explosive fragmentation is also supported by the fragmentation of the large

797 mineral grains observed in the samples (Figs. 4,5; e.g., Best & Christiansen, 1997; Bindeman,
798 2015).

799 In order to assess the emplacement conditions of the dacite unit, several temperature and
800 chemical proxies were measured from the surrounding sediments. The total organic matter
801 (TOC) record shows no systematic loss of TOC in the sediments surrounding the dacitic unit.
802 Moreover, no significant variations in $\delta^{13}C_{org}$ (Fig. 2) occur near the dacite unit and no
803 appreciable organic-matter maturation appears to have taken place near the dacite based on the
804 RockEval parameters (Tmax), which would be expected even at relatively low temperature
805 (<100 °C; Svensen et al., 2023; Bédard et al., 2023). Analyses performed on sediment samples
806 from directly overtop the dacite in borehole U1570D show high Hg concentrations (~350 ppb),
807 however, these concentrations remain within the variability of the rest of the analyzed samples.
808 Svensen et al. (2023) demonstrated that thermal alteration in intrusive aureoles can result in a
809 loss of sedimentary Hg, likely because the most common sedimentary Hg phases (organic-matter
810 bound Hg and HgS) rapidly volatilize at temperatures of 200–300 ºC, therefore, elevated Hg is
811 not consistent with thermal impacts from the dacite (e.g., Biester & Scholz, 1997).

812 Finally, samples were collected from directly at and within the mixing zone at the top and
813 base of the unit, as well as in a transect away from the contact and prepared for palynological
814 analyses. Samples in the mixing zone and adjacent to the dacite yielded abundant thermally
815 immature assemblages of acritarchs, dinocysts, pollen, and spores. These assemblages yielded a
816 Thermal Alteration Index (TAI; Gutjahr, 1966; Staplin, 1969) of 1+, values that were also
817 recorded from similar palynofloras 20 m further down the core. These TAI values are indicative
818 of temperatures of <45°C and confirm that the dacite did not thermally alter the sediments into
819 which it was recovered. This combined evidence from the sediments, along with the pyroclastic
820 nature of the unit, strongly argues against emplacement of the dacite as a liquid magmatic
821 intrusion. Although, emplacement as an invasive lava flow could explain the mingling textures
822 evident on the upper margin (Famelli et al., 2021), it is also inconsistent with the pyroclastic
823 nature of the dacite. The alternative, and preferred, interpretation is that the unit comprises a
824 deposit associated with an explosive pyroclastic density current (PDC; Branney et al., 2021).
825 Explosive pyroclastic density currents are known to be capable of flowing subaqueously if their
826 density exceeds that of the water in which they are erupted (Sparks et al., 1980a, b; White, 2000).
827 The flow of PDC's below water is in large part density-controlled, and, as such, the potential for

828   a PDC to flow into other fluids, such as muddy unconsolidated basin floor sediments, should be

829   equally controlled by density and other rheological properties, such as shear strength and

830   cohesion of water saturated sediments which will restrict the depth to which a PDC could

831   become invasive (e.g., Owen, 1987). The relatively sharp contact between the base of the dacite

832   and sediment below (Fig. 2E) with preserved sediment structures and local incorporation of

833   sediment clasts indicates some level of basal erosion and incorporation during the emplacement

834   of the dacite as a PDC (e.g., Roche et al., 2013). The emplacement dynamics of the dacite clearly

835   merit further study, however, we tentatively propose emplacement as a subaqueous PDC, which

836   exceeds the density of the uppermost layer of unconsolidated, mud-rich basin sediments,

837   promoting it to be partially invasive and resulting in local mingling with sediments.

6.1.2 Thermobarmetric and H$_2$O constraints

839   Ideally, we would construct the pseudosections and perform thermobarometric

840   calculations using the composition of the protolith (e.g., Álvarez-Valero and Waters, 2010) from

841   which the dacite was derived to estimate the pressure and temperature conditions and water

842   contents of formation. In our case, however, we do not have access to the composition of the

843   protolith. Because the textural and chemical characteristics of garnet, cordierite and alkali

844   feldspar that these minerals are peritectic phases (see equation 9), they should be in equilibrium

845   with the melt. The anorthite (An) contents of the plagioclase are more variable (Fig. S5a). We

846   compare plagioclase found in our samples with plagioclase grains found in lavas from El

847   Hoyazo, Spain (Hiwatashi et al., 2021). The occurrence of high K-volcanics in this province can

848   be considered as an analog for the formation of the dacitic unit studied here (see below).

849   Plagioclases in the lavas from El Hoyazo show a large compositional spread with An-rich

850   plagioclase (>80%) showing resorbed or patchy textures, intermediate compositions showing

851   oscillatory zoning, and An-poor (<50%) compositions occurring in homogeneous subhedral

852   grains. Hiwatashi et al. (2021) interpret this variability as evidence for magma mixing between

853   high-SiO2 dacite and andesite. Plagioclase observed in our samples overlap with the

854   compositions of the homogeneous grain interpreted as in equilibrium with a dacitic magma.

855   Hence, using the bulk rock composition, we consider that the pressure-temperature field that

856   reproduces the phase assemblage observed in our sample provides a good approximation for the

857   conditions of formation of the magma.

858   Partial melting of metapelitic rock during metamorphism commonly produces almandine

859   garnet, which has commonly been interpreted as a high-pressure (>7 kbar) peritectic or liquidus

860   phase in a hydrous, Al-rich magma (Green & Ringwood, 1968; Clemens & Wall, 1988; Harangi

861   et al., 2001; Sieck et al., 2019). Green (1977), however, demonstrated that the grossular and

862   spessartine content of almandine garnets are sensitive to pressure and that Ca and Mn-rich (> 4

863   wt% CaO and MnO) almandine garnets could have crystallized at pressures less than 5 kbar.

864   However, this cannot explain low-pressure signature recorded by the almandine garnet in our

865   samples as they are Ca-poor (~1 wt% CaO) and Mn-poor (~1.8 wt% MnO). Aranovich and

866   Podlesskii (1983) experimentally investigated the cordierite-garnet-sillimanite-quartz

867   equilibrium at 4–8 kbar to determine the coexisting garnet and cordierite equilibrium

868   compositions. At 4 kbar and 700°C, their experimental products have Fe-rich compositions

869   consistent with natural samples from their study. They also showed that the Mg content of garnet

870   and cordierite increases significantly with pressure from $Mg^{grt} = 0.10$ mol% and $Mg^{crd} = 0.44$

871   mol% at 4 kbar to $Mg^{grt} = 0.51$ mol% and $Mg^{crd} = 0.89$ mol% at 8 kbar. Compared to the Mg

872   content measured in garnet and cordierite grains in our study ($Mg^{grt} = 0.10 \pm 0.1$ mol% and Mg^{crd}

873     $= 0.41 \pm 0.02$ mol%), their results support the relatively low equilibration pressure calculated for

874   our samples. Additionally, Clemens and Wall (1981) observed garnet crystallization down to 1

875   kbar for temperatures 700–900 °C in their experiments for water-undersaturated, peraluminous

876   magmas, and in the last decade, several studies, through thermodynamic calculations and

877   characterization of melt inclusions (e.g., Acosta-Vigil et al., 2010; Bartoli et al., 2013a, 2013b),

878   have shown that peritectic garnet can also grow at low temperatures (≤ 700°C) and low pressures

879   (≤ 5 kbar).

880   Growth of peritectic garnet, cordierite, and alkali feldspar during anatexis of metapelites

881   is thought to result from the breakdown of biotite during dehydration melting (e.g., Cesare et al.,

882   2009; Ferrero et al., 2012; Stevens et al., 2007). Weinburg and Hasalová (2015) cite the

883   following reaction in metapelites and variable pressure and intermediate temperature (700–

884   800°C; Le Breton & Thompson, 1988; Spear, 1993):

885   Biotite + Quartz + Plagioclase + Aluminosilicate = Garnet/Cordierite

886   + Alkali Feldspar + melt   (8)
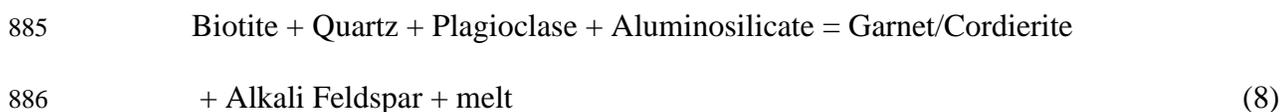

887   in which cordierite results from the subsequent breakdown of garnet (Stevens et al., 1995). The

888   absence of biotite in our sample, the dissolution texture observed on the margins of plagioclase

889   grains, and the existence of a garnet inclusion in cordierite support the proposed reaction for

890   peritectic garnet growth (Eq. 8). Our results are consistent with biotite dehydration melting,

891   because its absence in our samples suggests that the magma formed at temperatures higher than

892   the field of stability of biotite (<350 °C for <3 wt% H_2O).

893   The phase assemblage observed in our samples is only reproduced for bulk water

894   contents ≤ 3wt%. A water-undersaturated composition is additionally supported by the presence

895   of graphite in the assemblage and anhydrous cordierite grains suggested by high analytical totals

896   (Table 1). In fact, for any H_2O-bearing phase, such as melt or cordierite, to coexist with graphite,

897   it must have an $a_{H2O} < 1$ (Bartoli et al., 2013c). Although metapelitic anatexis at high temperature

898   (700–800°C) is facilitated by biotite dehydration melting and the release of water, experimental

899   studies by Holtz et al. (1992) show that the melt remains water-undersaturated. Additionally,

900   these water-fluxed, undersaturated melts are particularly buoyant, supporting rapid migration to

901   the surface (Holtz et al., 1992).

902   Using the pseudosection results for a magma with 1–3 wt% H_2O, the observed

903   phenocryst assemblage for our samples is stable at pressures of ~4–5 kbar and temperatures

904   higher than 750 °C, consistent with results obtained from thermobarometric calculations (Fig.

905   11). The pressures and temperatures recorded by the dacite phase assemblage are considered to

906   approximate the conditions of the last equilibrium state of the magma prior to rapid transport and

907   quenching. The limited compositional variability of the glass and mineral phases, as well as the

908   highly vesicular and glassy texture of the matrix, are interpreted to be consistent with rapid

909   emplacement and quenching. Therefore, we highlight that the recorded pressure-temperature

910   conditions may not represent the original melting conditions and the sample may have re-

911   equilibrated at depth along its ascent path (e.g., Álvarez-Valero & Waters, 2010).

912   We note that while crystallization and heat loss from the breakdown of garnet during the

913   decompression of magma should result in a lower temperature for Grt-Crd pairs than for Grt-Ilm

914   pairs (Sykes & Holloway, 1987), our samples record significantly higher temperatures for the

915   Grt-Crd pairs (Fig. 11). Hence, these results are consistent with a progressive melting process

916   happening at a relatively constant low pressure and variable high temperatures, with garnet-

917 ilmenite pairs recording the early stage of melting and garnet-cordierite pair the final stage of

918 melting. Therefore, we consider ~4.5 kbar, ~800 °C, and 1–3 wt% H_2O to be a good

919 approximation of the conditions for the average peak temperature during the formation of the

920 dacitic magma. Because seismic profiles of the Mimir High show the sediment cover is relatively

921 thin where the dacite was collected (Fig. 2), we can assume this pressure range is more likely to

922 result from generation at depth within the crust rather than from intrusion into the sediments

923 (Abdelmalak et al. 2017; Polteau et al., 2020).

924 *6.1.3 Age constraints*

925 McKenzie et al. (2018) suggest that the REE abundances in zircon preserve a record of

926 the composition of silica-rich parental melts since REE diffusion in zircon is slow and Zr is

927 abundant and incompatible in silica-rich melts. This means that variation in REE patterns, like

928 Eu anomalies, are representative of different parental magmas. Compared to population #1,

929 population #2 zircons show significantly more variable Eu anomalies (Fig. S9), indicating they

930 come from different sources and are therefore inherited rather than crystallized directly from the

931 dacite. The higher variability of population #2 is also observed on the shape components of the

932 trends (i.e., lambda coefficients; Anenburg & Williams, 2022), even when the Ce and Eu

933 anomalies are not included (Fig. S9C). The more restricted range of concentrations observed in

934 population #1 is consistent with crystallization from a single melt phase, likely during peritectic

935 growth of garnet and cordierite. The spatial distribution of these populations on CL images of the

936 individual zircons indicates that population #1 analyses are more often located on the rims of

937 grains, while population #2 analyses are either in or on the edge of darker cores (Fig. 9A). This

938 suggests that the population #1 analyses likely represent new growth from the dacite magma

939 reaching zircon saturation and that the calculated weighted average of these analyses (54.6 ±1.1

940 Ma) is interpreted as the magmatic age. We note that as the analyzed zircons were found as

941 inclusions in garnet and cordierite, this age corresponds to the maximal age (not storage at depth)

942 for the eruption age.

943 The kernel density estimate (KDE) plot of the spot ages from population #2 shows zircon

944 as old as 2500 and 1700 Ma, with additional peaks at 100–400 Ma (Fig. S7A). This is in range of

945 what is expected for inherited grains on the Vøring Plateau, with possible contributions from

946 East Greenland sources (450–350 Ma, 2000–1700 Ma, and 3800–2500 Ma) and Norwegian

947 sources (450–350 Ma, 1250–900 Ma, and 1750–1500 Ma; Fonneland et al., 2004). However, it

948 should be noted that our calculations only include 11 analyses for population #2 and are

949 therefore unlikely to be a statistical representation of the entire spectrum of inheritance ages.

950 Zircons tend to incorporate HREEs relative to LREE and middle REEs (MREEs) from

951 their host melt (McKenzie et al., 2018). Chondrite-normalized (McDonough & Sun, 1995) REE

952 spectra for zircon measured in our samples are broadly consistent with this magmatic zircon

953 trend with steep positive slopes (Fig. S9A). There are a couple of analyses that have elevated

954 LREE concentrations. Because REE diffusion in zircon is slow, this may be the result of

955 overlapping inclusions during analysis or can be an effect of hydrothermal alteration as an influx

956 of LREE (Hoskin, 2005; McKenzie et al., 2018). The trace element concentrations for these

957 analyses do not suggest analytical overlap with other minerals and both are in older population

958 #2 grains. Therefore, we suggest their LREE concentration results from hydrothermal alteration,

959 and neither of these zircon grains are used in further interpretations.

960 6.2 Regional implications

961 *6.2.1 The evolution of rifting on the Vøring Plateau*

962 Crustal anatexis at magma-rich margins during rifting is often considered to be a lower

963 crustal process, facilitated by a mafic magmatic underplate. Crustal magmas are then transported

964 to an upper crustal reservoir or to the surface with varying degrees of re-equilibration and crustal

965 assimilation during transport (e.g., Vissers et al., 1995; Pederson et al., 1998 and references

966 therein; Platt et al., 1998; Duggen et al. 2004; Álvarez-Valero & Kriegsman, 2007; Thybo &

967 Artemieva, 2013 and references therein; Neumann et al., 2013). Dacite generation through

968 underplating has been described by Luo et al. (2018) as a result of crustal anatexis from heat

969 provided by mantle-derived basaltic magmas. The basaltic magmas mix with the crustal melts to

970 produce andesitic magmas, which can evolve to strongly peraluminous dacitic magmas by

971 stalling, fractionating, and the assimilation of anatectic melts of surrounding metasedimentary

972 rocks. The presence of underplated material at the base of the crust is often supported by seismic

973 reflection images of thick, lower crustal bodies with high velocities ($V_P > 7$ km) that are

974 characteristic of magma-rich margins (Kelemen and Hobrook; 1995; White et al., 1987, 2008;

975 Gac et al., 2022). In the Jameson Land Basin in East Greenland and in the Artic Basin of North

976 Greenland, the underplated material has also been proposed as a source of melt generation

977 (Thorarinsson et al., 2011; Eide et al., 2022).

978 Our thermobarometric calculations suggest, however, that the dacite collected at site

979 U1570 was not produced in the lower crust but was instead generated in the upper crust (< 18 km

980 depth assuming a continental crust density of 2.8 g/cm^3). The bulk trace elements composition of

981 the samples (Fig. 3B) also supports an upper crust origin. The enrichment in Cs, in particular, has

982 been proposed as a discriminating factor between the upper and the lower crust (Meyers et al.,

983 2009). No evidence of deeper crustal processes is observed. This may be explained by chemical

984 re-equilibration in an upper crustal reservoir of a magma formed at depth. For instance, this

985 scenario has been favored to explain the formation of the high-K volcanic lavas in the NVP, SE

986 Spain. Thermobarometric calculations performed on enclaves of the high-K volcanic rocks from

987 the El Hoyazo and Mazarrón volcanoes suggest melting pressures of 7 kbar (Cesare et al., 1997;

988 Cesare & Gómez-Pugnaire, 2001) and 4 kbar (Cesare et al., 2003), respectively. The difference

989 in pressure recorded at the two volcanoes is attributed to varying depths of magma stagnation in

990 the crust. The dacite from our study presents mineral phase compositions that match the mineral

991 phases of the NVP high-K volcanic rocks (Figs. 6, 7, 8) and records pressure and temperature

992 conditions of anatexis similar to those reported for the Mazarrón volcano, consistent with an

993 upper crustal origin. Additionally, in comparison to the NVP, the glass composition (Fig. 3) in

994 the Site U1570 dacite is more homogenous, which suggests that magma storage for our samples

995 was long enough to approach chemical equilibrium. However, temperature recorded by the

996 garnet-ilmenite and the garnet-cordierite pairs suggest they formed as a result of heating at a

997 constant pressure rather than through decompression processes as we would expect for migration

998 from the lower to upper crust. We propose the Site U1570 dacite is the product of low pressure

999 (<5 kbar) partial melting of crustal metapelites on a thinned lithosphere, consistent with previous

1000 assumptions on the origin of silicic magmatism in the NE Atlantic (e.g., Abdelmalak et al., 2016;

1001 Eldhom et al., 1987; Sinton et al., 1998; Viereck et al., 1988) as the result of crustal anatexis at

1002 low pressure. This scenario is also consistent with a study of the Isle of Rum, in which

1003 rhyodacites were interpreted to be produced by melting amphibolite rather than deep crustal

1004 granulite (Meyer et al., 2009b), and with ODP Site 642E dacite trace element data that are

1005 compatible with melting Caledonian metasedimentary rocks (Viereck et al., 1988). Our results

1006 also provide evidence for

1007   Previously published Ar-Ar dating on plagioclase from the dacite collected by ODP in

1008   hole 642E did not provide a precise age of eruption of the silicic magmatism (57–51.5 Ma;

1009   Sinton et al., 1998). It is, however, consistent with the age obtained on dacitic lava recovered

1010   from the North Rockall Trough (Darwin Complex; Fig. 3; Morton et al., 1988a) indicating an age

1011   ~55 Ma (Sinton et al., 1998 and references therein) and both are coincident with the magmatic

1012   age reported in this study. Importantly, the weighted mean U-Pb date interpreted as the age of

1013   zircon growth in this study (54.6 ± 1.1 Ma) postdate the age of the PETM (56–55.8 Ma; Jones et

1014   al., 2023).

1015   Dacite recovered at ODP Site 642E is thought to have been emplaced before the peak of

1016   magmatism (Abdelmalak et al., 2017), and stratigraphic relationships indicate that the basalt

1017   overlying the silicic lavas from the North Rockall Trough and the Vøring Plateau erupted shortly

1018   after the silicic magmas (Sinton et al., 1998 and references therein). This resulted in

1019   interpretations suggesting the end of silicic magmatism is coeval with the onset of the main

1020   basaltic phase, potentially due to a change of extension rate (e.g. Abdelmalak et al., 2016; Sinton

1021   et al., 1998). Interestingly, the dacite recovered at Site U1570 is not overlain by basaltic

1022   magmatism but was rather emplaced at the surface in a shallow marine setting. At Mimir High,

1023   the overall palynofacies of the sediments is dominated by terrestrial elements (pollen, spores, and

1024   phytodebris) in addition to marine elements (dinoflagellate cysts), suggesting that the

1025   depositional environment was coastal for most of the Paleocene and Eocene (Planke et al., 2023).

1026   This demonstrates that the coastal environment was sustained despite being an active depocenter,

1027   consistent with substantial subsidence of the continental crust during extension. The

1028   emplacement of the dacite within these sediments indicates this extension remained active during

1029   and after the emplacement of this dacite.

1030   Several studies (e.g., Peron-Pinvidic et al., 2013, Tugend et al., 2018; Gillard et al., 2019;

1031   Ferrand, 2020) have proposed that magma-rich rift margins may go through a period of

1032   hyperextension, suggesting that extreme crustal thinning does not preclude the emplacement of a

1033   high volume of magmatism. Tugend et al. (2018) suggested that when the distinction between

1034   magma-poor and magma-rich margins reflect the magmatic productivity, the overall evolution

1035   before breakup may only reflect the timing of decompression melting relative to thinning of the

1036   margin. In this context, Ferrand (2020) proposed that the Vøring margin was initiated as a

1037   magma-poor margin and was subsequently affected by hotspot-induced magmatic processes and

1038   overprinted by volcanic activity. Evidence for silicic magmatism in the Northeast Atlantis as old

1039   as ~62 My ago, with tuff interlayers between basalt flows on the Isle of Muck (Emeleus et al.,

1040   1996) dated at 62.8–62.4 Ma (Pearson et al., 1996) and ash layers in sediments of the North Sea

1041   (Knox & Morton, 1998; Morton et al., 1998 that indicate mixing between silicic and basaltic

1042   magmatism dated at 62–60 Ma. Together, these ages suggest a longer period of crustal anatexis

1043   off the coast of Norway during rifting of the Northeast Atlantic. Additionally, the occurrence of

1044   dacitic magmatism on the mid-Norwegian margin, either overlain by subaerial magmatism (ODP

1045   hole 642E and the North Rockall Trough) or emplaced in a sediment of an early Eocene age

1046   (IODP Expedition 396, Site U1570), indicates that magmatism not only occurred at the zone of

1047   plate separation, but also landward of the ocean-continent transition on the European side. We

1048   propose that the pre-breakup phase during the development of the Vøring margin was associated

1049   with significant continental lithospheric extension. This extension resulted in low-pressure

1050   melting of metasedimentary rock to generate silicic magmas that erupted later.

1051   *6.1.2 Implications for the Paleocene-Eocene carbon cycle pertrubations*

1052   Excess magmatism, thermogenic gas release and sediment melting from contact

1053   metamorphism around sills have been invoked to explain the carbon cycle perturbations that

1054   occur throughout the late Paleocene and early Eocene, most notably the PETM, the largest of a

1055   series of global warming episodes (e.g., Svenson et al., 2004; Westerhold et al., 2020). The

1056   PETM was marked by rapid surface warming (~5 °C), ocean acidification, and the release of

1057 ^{13}C-depleted carbon into the oceans and atmosphere, evidenced by a sharp decrease in

1058   sedimentary δ^{13}C, a negative Carbon Isotope Excursion (CIE; Kennet & Scott, 1991; Zeebe et

1059   al., 2009). Estimations provided by mass balance calculations suggest the PETM CIE was the

1060   result of the injection of 3,000–14,900 gigatons (Gt) of ^{13}C-depleted carbon (Zeebe et al., 2009;

1061   Gutjahr et al., 2017; Haynes and Hönisch 2020) most likely over a geologically rapid (few

1062   thousand years) time frame (Zeebe et al., 2016; Kirtland-Turner & Ridgewell, 2016). While

1063   sedimentary proxy and stratigraphic evidence support a contribution from volcanic outgassing

1064   (e.g., Frieling et al., 2016; Jones et al., 2019; Kender et al., 2021), it remains unclear whether the

1065   volcanic source would provide the timing, composition, magnitude, and rate of outgassing

1066   required to generate the CIE (Haynes & Hönisch, 2020; Gutjahr et al., 2017). It has been

1067   proposed that mafic intrusions related to the excess magmatism of the mid-Norwegian margin

1068   resulted in hydrothermal vent complex formation and direct emission of CO_2 into the atmosphere

1069   (e.g., Gernon et al., 2022) or contact metamorphism of organic-rich ocean sediments and

1070   subsequent explosive release of large amounts of methane with a ^{13}C-depleted isotope signature

1071   (δ^{13}C; e.g., Svensen et al., 2004; Frieling et al., 2016). Rampino (2013) further suggested that the

1072   NAIP emplacement may have contributed more thermogenic gases by anatectic melting of

1073   organic-rich sediments rather than pure contact metamorphism. The authors proposed that dacitic

1074   flows observed throughout the Norwegian continental margin may be the direct product of this

1075   process. Our dacitic sample from the Mimir High does not support Rampino (2013)'s hypothesis.

1076   In fact, the sediments in contact with the dacite indicate no thermal alteration, which suggests

1077   that its emplacement did not mobilize or volatilize significant amounts of carbon from

1078   surrounding sediments. While the graphite film observed on some grains suggests that minor

1079   amounts of fluid-deposited carbon may be present (e.g., Luque et al., 1993), the presence of

1080   graphite grains (as inclusion or disseminated in the sample) is consistent with a restitic phase that

1081   has been entrained in the melt (Zeck 1970, 1992). Hence, the presence of graphite is likely

1082   inherent to the nature of protolith of our samples, a graphitic metapelite, rather than a product of

1083   melting or burning organic matter.

1084   However, this does not imply the formation of the Site U1570 dacite did not release CO_2.

1085   Cesare et al. (2005) showed that in relatively reducing conditions (as in graphitic metapelites),

1086   biotite is the only source of Fe^{3+}, with the melting reaction of biotite is important to iron

1087   reduction. As the melt produced during the reaction is relatively iron-poor (Table 1), biotite

1088   breakdown is accompanied by carbon oxidation and the production of CO_2. The amount of CO_2

1089   produced in this way, however, is likely too small to be a significant contribution to the PETM.

1090   Additionally, the zircon inclusions record post-PETM U-Pb magmatic ages. Sill intrusions and

1091   hydrothermal vent complexes can release large volatile concentrations into the atmosphere and

1092   may have contributed to the onset and longevity of the PETM (Frieling et al., 2016; Berndt et al.

1093   2023), but the dacite sample outlined by this study is not an example of this. In fact, the long

1094   period of silicic magmatism (~62–54.6 Ma) in the Northeast Atlantic highlighted here warrants

1095   caution in including NAIP-related thermogenic carbon released from eruptions into wet

1096   sediments in carbon emission calculations.

5 Conclusions

The garnet and cordierite-bearing dacite sampled during IODP Expedition 396 in boreholes U1570A and U1570D was likely emplaced as a high-density pyroclastic current into wet, unconsolidated sediments in a shallow coastal environment after the onset of the PETM. This is evidenced by the folded, elongated glassy pyroclastic textures, local mingling with sediment and preserved sediment clasts, and highly fragmented phenocrysts. The chemical signatures of the peritectic garnet and cordierite grains suggest an upper crustal, metapelitic protolith. This is further supported by the inheritance patterns observed in the zircon U-Pb ages that match inherited grains on the Vøring Plateau. Our thermodynamic results suggest the magma is water undersaturated (≤ 3 wt% H_2O) and indicate low pressure (<5 kbar), high temperature (~800 °C) anatexis in the upper continental crust.

We propose this dacite is a crustal anatectic product of an intense and long (> 7 Myr) phase of continental stretching that preceded the main phase of basaltic magmatism emplacement, that was later (< 54.6 ±1.1 Ma) emplaced on top of unconsolidated wet sediments. Implications of lithospheric thinning in excess-magmatic margins should be considered in tectonic reconstructions for the evolution of the North Atlantic rift margin.

Data Availability Statement: All the data are shared in tables in the main text and as supplementary tables attached with this manuscript and will be archived on Zenodo upon acceptance.
